
The latter can also be obtained by direct coupling of diazonium salts with esters of acetylsuccinic acid. The azo compounds formed as intermediates rearrange with cleavage of the acyl group to give the corresponding hydrazone derivatives:

2-Aryl-3-Methyl-5-Pyrazolones. If equimolar quantities of diketene are treated with arylhydrazines in dilute acetic acid, 2-aryl-3-methyl-5-pyrazolones are obtained as the main products [17]. These have not, however, yet achieved industrial importance.

3-Aryl-1-Methyl-5-Pyrazolones (Isopyrazolones). Isopyrazolones are defined as compounds in which the positions of the aryl and methyl groups of 1-aryl-3-methyl-5-pyrazolones are exchanged. 1-Methyl-3-phenyl-5-pyrazolone [*41927-50-8*] (**9**), which melts at 214 °C, is, however, very similar to its isomer (**4**) (*mp* 128–129 °C) in its other properties. It can be obtained, for example, by warming ethyl 3-oxo-3-phenylpropionate [*94-02-0*] with methylhydrazine [*60-34-4*] [18]:

4-Amino-1-Aryl-3-Methyl-5-Pyrazolones. Arylmethylpyrazolones react with nitrous acid to give 4-isonitroso compounds, and with nitric acid to give 4-nitro compounds. Both types of compound can be reduced with tin–hydrochloric acid, zinc–glacial acetic acid, sulfite, or catalytically with hydrogen to give the corresponding 4-aminopyrazolones. The 4-amino compound can also be produced by reductive cleavage of azo dyes derived from pyrazolones. 4-Aminopyrazolones are only stable in the form of their salts. The free bases are very sensitive to oxidation. Thus, for example, 4-amino-1-phenyl-3-methyl-5-pyrazolone [*5142-72-3*] reacts further to give the red dye Rubazonic acid (**10**):

10 [*909-59-1*]

5-Iminopyrazolones. As spectroscopic investigations have shown, these compounds are actually 5-aminopyrazoles. Nevertheless they are mostly described in the literature as imino compounds in analogy to the pyrazolones. 1-Phenyl-3-methyl-5-iminopyrazolone (**11**) is formed on treatment of butadienenitrile [*1001-56-5*] with phenylhydrazine [*100-63-0*] in methanol and subsequent warming with hydrochloric acid [19]:

11 [*6401-97-4*]

Another method involves the reaction of the corresponding 5-chloropyrazolium chlorides with ammonia or amines. For example, the reaction of phosphorus oxychloride with Antipyrin (**6**) gives 5-chloro-2,3-dimethyl-1-phenylpyrazolium chloride. The latter can be converted into the imino compound **12** by heating with ammonia or amines at moderate temperatures. At higher temperatures methyl-group cleavage occurs to give the imino compound **13** [20].

12 **13**

3,5-Dioxypyrazolidines. 1,2-Diphenyl-3,5-pyrazolidinedione [*2652-77-9*] is obtained by condensation of diethyl maleate with hydrazobenzene in the presence of sodium ethoxide [21].

4-Butyl-1,2-diphenyl-3,5-pyrazolidinedione (phenylbutazone) (**14**) and 4-butyl-1-(4-hydroxyphenyl)-2-phenyl-3,5-pyrazolidinedione (oxyphenbutazone) (**15**) also belong to the pyrazolidinedione group. As Butazolidin [*50-33-9*] and Tanderil [*129-20-4*] they have become important in the treatment of rheumatism.

14 **15**

4. Environmental Protection

Pyrazolones are widely produced by the reaction of the corresponding amines with acetoacetic esters, acetoacetamides, or esters of acetylsuccinic acid, without isolation of the intermediate diazonium salts, hydrazines, and hydrazones. Wastewater is only produced in the final stage during the isolation of the pyrazolones. Depending on the product the wastewater has a COD of 1 – 50 g O_2/L. The COD elimination is ca. 50 % for most pyrazolones; pollution of the wastewater by hydrogen sulfate and sodium chloride poses additional problems. The biodegradability of pyrazolones is generally very poor. Some pyrazolones are even classified as toxic to bacteria and fish (EC_{50} 200 – 1000 mg/L, 3 – 6 h; LC_{50} 10 – 500 mg/L, 48 h) [22], so that special wastewater-treatment methods are necessary. For example, the mother liquors of nonbiodegradable pyrazolones can be evaporated and the residue incinerated. Oxidative cleavage of the pyrazolone ring into more readily biodegradable fragments or charcoal adsorption with subsequent incineration are conceivable. For all these processes the high salt content of the wastewater is problematic.

5. Quality Specifications

Phenylmethylpyrazolone (**4**), which is used as a starting material for various pharmaceuticals, should not contain more than 0.1 % bispyrazolone [*7477-67-0*]. The formation of this byproduct must therefore be hindered by avoiding an excess of phenylhydrazine during production. Furthermore, special quality specifications apply for various pyrazolones depending on the use. For pyrazolones which are used as precursors in dye production, a pure material content of 98 – 99 % is sufficient. Varying quantities of inorganic salts do not interfere here. Pyrazolones are further processed when both wet (water content 25 – 35 %) and dry (water content <0.5 %).

6. Analysis

The pyrazolone content can be determined by coupling with diazotized *m*-nitroaniline solution in weakly acidic, acetate-buffered solution. The end point of the titration can be recognized by spotting against H-acid solution (red coloration). The content can also be determined, by potentiometric titration with an 0.1N KBr –$KBrO_3$ solution in a hydrochloric acid medium. Other components which may be present are determined by HPLC and TLC.

7. Storage and Transport

Pyrazolones are sold as both wet and dry products. The wet product is packed in metal drums with polyethylene liners (100 or 130 kg), and the dry product also in paper sacks (25 kg) or big

bags (200 – 250 kg). Dry pyrazolones can generally be stored for an unlimited time under appropriate conditions (at least 2 years). Wet pyrazolones can be stored for at least 6 months. Pyrazolones are nonhazardous materials, so no special international regulations and classifications for ship, rail, or road transport have been imposed. However, national transport regulations, which may differ from these, must be adhered to.

8. Uses

Pyrazolones are used almost exclusively as precursors for pharmaceuticals and dyes.

8.1. Pharmaceuticals

Among the pyrazolone derivatives there are a large number of compounds with antipyretic and analgesic action. The following are some of the most important ones: phenazone (Antipyrin), aminopyrin (Pyramidon), propyphenazone (Isopropylphenazone), noraminopyrine methane-sulfonate sodium (Novalgin), phenylbutazone (Butazolidin), nifenazone (Nicopyron), oxyphenbutazone (Tanderil), morazone (Tarugan), isopyrin, and piperylone (→ Analgetics and Antipyretics, Chap. 3.). The parent substance of almost all these compounds is 1-phenyl-3-methyl-5-pyrazolone methylated in the 2-position (Antipyrin **6**).

8.2. Dyes and Pigments

As early as one year after the discovery of pyrazolone, Tartrazine, the first dye based on pyrazolone, was produced by Ziegler and Lochner [4]. Tartrazine is still used as a dye for foodstuffs. The industrially important pyrazolone dyes are almost exclusively azo dyes. The pyrazolone molecule couples with diazonium compounds in the 4-position to give azo dyes and pigments that exhibit good color strength, lightfastness, and other favorable properties.

Besides their use in leather and wool dyeing (→ Azo Dyes) pyrazolones have also found use as precursors for cotton dyes and for pigments and dyes for synthetic fibers and plastics. Pyrazolones are thus found among nearly all types of dye. For wool dyes, solubilizing sulfo and carboxyl groups are used which can be substituents both in the pyrazolone and in the coupling component. The capacity of pyrazolone derivatives to form complexes with chromium is exploited in the production of chrome dyes.

By introducing so-called reactive components into pyrazolones or into the coupling component, reactive dyes for cellulose fibers are obtained (→ Reactive Dyes). Pyrazolone derivatives without solubilizing groups are suitable as precursors for pigments. For coloring synthetic fibers, either pyrazolone pigments are used or pyrazolone dyes are dissolved in the spinning solution.

Pyrazolones are gaining increasing importance as photographic dyes, particularly in sensitizer dyes and as precursors for color couplers and color filters (→ Photography). In addition pyrazolones and related compounds have proved to be good developing agents for black and white and Polaroid photography.

8.3. Crop Protection

Pyrazolones with fluorine- or trifluoromethyl-substituted aryl groups in the 1-position have become important as herbicides and fungicides [23].

9. Economic Aspects

Pyrazolones are used almost exclusively as precursors for pharmaceuticals and dyes. No data are available on production capacity, but it can be estimated at ca. 20 000 t worldwide. About 16 000 – 17 000 t of pyrazolones are produced annually, of which ca. 9000 t phenylmethylpyrazolone (**4**) are used for pharmaceuticals. The rest is divided between about 10 – 15 other pyrazolones, which are required for dye and pigment production including ca. 3000 t of carboxypyrazole acid **4** (see page 8) for the production of Tartrazine. The most important producing countries are Germany, Switzerland, and the United States.

10. Derivatives

1-Phenyl-3-methyl-5-pyrazolone [*89-25-8*] (**4**), $C_{10}H_{10}N_2O$, M_r 174.20, *mp* 128–129 °C, bp_{17mbar} 191–192 °C, forms colorless crystals that are almost insoluble in cold water, ether, and petroleum ether, but soluble in alcohol, acids, and alkalis. With heavy metal ions, salts are formed, which are mostly deeply colored [24]. Phenylmethylpyrazolone reduces ammoniacal silver nitrate, reacts with nitrous acid to give a 4-oximino compound [25], and gives characteristic color reactions with benzotrichloride [26]. On methylation, 2,3-dimethyl- [*60-80-0*], 3,4-dimethyl- [*17900-68-4*], 2,3,4-trimethyl- [*5677-84-9*], and 3,4,4-trimethyl-1-phenyl-5-pyrazolone [*947-82-0*] and 5-methoxy-3-methyl-1-phenyl-1*H*-pyrazole [*27349-35-5*] are formed, depending on the reaction conditions [27]. The industrial production of this pyrazolone, which is produced in large quantities, starts with ethyl acetoacetate and phenylhydrazine, which are converted into the desired pyrazolone in one reaction step. Another method involves the reaction of acetoacetamide solution with aniline without isolation of the intermediates [28].

Phenylmethylpyrazolone is industrially the most important pyrazolone. It is used in large quantities for the production of Antipyrin (**6**) and related pharmaceuticals. In the colorant industry it is used as a coupling component for azo pigments and dyes. With diazotized dichlorobenzidine, for example, it is coupled to give Pigment Orange 13, which is used in the rubber and plastics industry. Phenylmethylpyrazolone is also a coupling component in Solvent Yellow 16, an oil-soluble dye, and in Mordant Yellow 30, a chrome dye.

***p*-Tolylmethylpyrazolone** [*86-92-0*], 1-(*p*-tolyl)-3-methyl-5-pyrazolone, $C_{11}H_{12}N_2O$, M_r 188.20, *mp* 137–138 °C, forms colorless crystals from water or cyclohexane. It is readily soluble in alcohol, glacial acetic acid, and benzene, but sparingly soluble in cold water [29].

It is produced from *p*-tolylhydrazine and acetoacetamide in acidic solution or directly from *p*-toluidine without isolating the intermediates. Tolylmethylpyrazolone is used for the production of pigments. Coupling with diazotized *o*-dianisidine gives Pigment Red 37, which is used in the plastics and rubber industry. It is also the coupling component in Pigment Orange 34, which is used in textile printing and paints.

Pyrazole acid 4 [*89-36-1*], 1-(4-sulfophenyl)-3-methyl-5-pyrazolone, $C_{10}H_{10}N_2O_4S$, M_r 254.26, *mp* 320 °C (dec.), forms colorless crystals which are sparingly soluble in alcohol, glacial acetic acid, and cold water, but readily soluble in aqueous alkali. It gives an intense red coloration with iron(III) chloride solution [30].

Pyrazole acid 4 is produced either from phenylhydrazine-4-sulfonic acid or from sulfanilic acid with acetoacetamide solution, without isolation of the intermediates.

Pyrazole acid 4 is used as a coupling component for azo dyes in many areas of the textile industry. For example, Acid Yellow 11, Acid Yellow 25, and Acid Yellow 117 are used for wool dyeing; and Direct Orange 1, Direct Yellow 16, and the reactive dyes Reactive Yellow 15, Reactive Yellow 17, and Reactive Yellow 24, for cotton dyeing. Mordant Yellow 8 and Mordant Orange 35 are chrome dyes.

Oxyethylsulfonepyrazolone [*21951-34-8*], 1-(4-β-hydroxyethylsulfonylphenyl)-3-methyl-5-pyrazolone, $C_{12}H_{14}N_2O_4S$, M_r 282.25, *mp* 172 °C (dec.), forms reddish crystals which are readily soluble in hot water and in aqueous alkalis.

The production is carried out by the usual process starting from the corresponding hydrazine

and acetoacetic ester or acetoacetamide. This pyrazolone is used as the reactive dye component in Reactive Yellow 13, Reactive Yellow 31, Reactive Yellow 37, Reactive Yellow 96, and Reactive Orange 7.

Carboxypyrazole acid 4 [*118-47-8*], 1-(4-sulfophenyl)-5-pyrazolone-3-carboxylic acid, $C_{10}H_8N_2O_6S$, M_r 284.23, is readily soluble in hot water and aqueous alkalis, crystallizes with 2 mol water, and gives a violet coloration with iron(III) chloride solution [31].

It is produced by treating the sodium salt of ethyl oxaloacetate with phenylhydrazine-4-sulfonic acid and warming the reaction product with aqueous sodium hydroxide, which results in ring-closure and simultaneous hydrolysis of the ester group to give the free carboxylic acid. This pyrazolone can also be produced by treatment of diazotized sulfanilic acid with diethyl acetylsuccinate. The carboxylic acid ester obtained is subsequently hydrolyzed with sodium hydroxide [32].

Carboxypyrazole acid 4 is used extensively in the production of Tartrazine (Food Yellow 4), the oldest pyrazolone dye, which is used to dye foodstuffs yellow. This pyrazolone is also used in the production of reactive dyes and is, for example, the coupling component in Reactive Yellow 23, Reactive Yellow 42, Reactive Orange 74, and Reactive Brown 16. It is present as a copper pigment in Reactive Black 31.

Carbethoxypyrazolone [*89-33-8*], ethyl-1-phenyl-5-pyrazolone-3-carboxylate, $C_{12}H_{12}N_2O_3$, M_r 232.22, *mp* 185 – 186 °C, forms colorless crystals which are sparingly soluble in water and ether, but soluble in alcohol [33].

It is produced by reacting the sodium salt of ethyl oxaloacetate with phenylhydrazine or by reaction of diethyl acetylsuccinate with diazotized aniline [34]. It is principally used as a component of Pigment Red 38 in the rubber and plastics sector, in particular for polystyrene and polyethylene.

Iminopyrazolone [*6401-97-4*], 1-phenyl-3-methyl-5-iminopyrazolone (**11**), $C_{10}H_{11}N_3$, M_r 173.21, *mp* 117 – 119 °C, is readily soluble in hot alcohol and chloroform. The chlorohydrate [*20737-88-6*] is a crystalline powder, *mp* 199 – 200 °C, which is readily soluble in water and alcohol [35]. Production involves treatment of butadienenitrile with phenylhydrazine in methanol and warming the reaction mixture with aqueous hydrochloric acid [19], or refluxing 5-methylisoxazole-3-carboxylic acid [*3405-77-4*] with phenylhydrazine [36]. Iminopyrazolone is used in cotton dyeing as a coupling component in Direct Red 180 in the form of the copper complex.

Phenazone [*60-80-0*], 1-phenyl-2,3-dimethyl-5-pyrazolone, Antipyrin (**6**), $C_{11}H_{12}N_2O$, M_r 188.22, *mp* 113 – 114 °C, forms colorless crystals which are readily soluble in water, alcohol, and chloroform, and sparingly soluble in cold toluene and diethyl ether [37]. Production involves methylation of phenylmethylpyrazolone (**4**) with dimethyl sulfate in the melt [38]. Besides its major industrial importance as a starting material for Pyramidon and Novalgin, Antipyrin is used almost exclusively in the area of pharmacology as the analgesic component in combination preparations or in the form of its salts (→ Analgesics and Antipyretics, Chap. 3.).

Aminopyrin [*58-15-1*], 1-phenyl-2,3-dimethyl-4-dimethylamino-5-pyrazolone, Pyramidon, $C_{13}H_{17}N_3O$, M_r 231.29, *mp* 107 – 109 °C, colorless crystals, readily soluble in alcohol and chloroform, moderately soluble in benzene, ether, and cold water [39].

In the production process Antipyrin is nitrosated in the 4-position, reduced to the 4-amino compound, and subsequently converted into the

4-dimethylamino compound by refluxing with formic acid and formaldehyde [40].

Pyramidon has a broad spectrum of activity and surpasses Antipyrin in its analgesic and antipyretic potency. In animals and humans the compound undergoes extensive metabolization. Unchanged Pyramidon has not been detected in excreta. Up to 3 % is excreted in the urine as the red dye, Rubazonic acid [*909-59-1*]. Because its toxicity is 4 – 5 times greater than that of Antipyrin, Pyramidon has now mostly disappeared from the pharmaceuticals market. However, it is still used as a double compound with barbiturates, which results in detoxification.

Propyphenazone [*479-92-5*], 1-phenyl-2,3-dimethyl-4-isopropyl-5-pyrazolone, $C_{14}H_{18}N_2O$, M_r 230.30, *mp* 103 °C, forms colorless crystals which are readily soluble in alcohol and sparingly soluble in cold water [41].

It is produced by condensation of phenylmethylpyrazolone (**4**) with acetone in the 4-position to give the isopropylidene compound, which is then converted into the 4-isopropyl compound by catalytic hydrogenation over a nickel catalyst. The subsequent methylation at N-2 is carried out with dimethyl sulfate at 125°C [42]. As an effective analgesic and antipyretic propyphenazone is a component of many mixed preparations, of which Melabon and Saridon are the best known.

Dipyrone [*68-89-3*], sodium 1-phenyl-2,3-dimethyl-5-pyrazolone-4-methylamino-methylsulfonate, Novalgin, Metamizol, $C_{13}H_{16}N_3O_4SNa \cdot H_2O$, M_r 351.35, *mp* 223 – 224 °C (dec.), is a colorless substance that forms a monohydrate. It is readily soluble in water and methanol, and practically insoluble in ether and chloroform.

The aqueous solution is neutral and becomes yellow with time, although there is no change in activity. On addition of nitrous acid the solution becomes blue and then green [43]. Dipyrone is produced from 4-aminoantipyrin, an intermediate in the synthesis of Pyramidon. This is reacted with benzaldehyde and then with dimethyl sulfate to give 4-methylaminoantipyrin. The latter is warmed with sodium hydrogensulfite and formaldehyde to give dipyrone [44]. The free acid [*50567-35-6*] can be produced by passing sulfur dioxide through an alcoholic solution of 4-aminoantipyrin and formaldehyde [45]. With inorganic and organic bases this acid forms salts, of which the calcium and quinine salts have proved to be particularly useful as components of Novalgin – quinine in the treatment of acute infections [46].

11. Toxicology

Pyrazolones are of low toxicity, so they do not present a direct health hazard. For all the pyrazolones investigated so far the acute oral toxicity (LD_{50}, rat) is >2000 mg/kg; for many pyrazolones the values are considerably higher, e.g., carboxypyrazole acid 4, 15 000 mg/kg; *p*-tolylmethylpyrazolone, 7450 mg/kg; and 2,5-dichloropyrazole acid 4, 17 227 mg/kg [47]. However, skin and eye contact should be avoided. When handling dry pyrazolones a dust mask should be worn to prevent inhalation. Contaminated clothing should be changed immediately. MAK values have not been set for pyrazolones.

1. Introduction

Pyridine, C_5H_5N, is a six-membered heterocyclic compound containing one nitrogen atom. Pyridine and its homologues are commonly called pyridine bases. The first pyridine derivative, 2-methylpyridine (α-picoline; *pix*, Latin = pitch) was isolated from coal tar in 1846 by Anderson [1]. In 1851, Anderson obtained pyridine (*pyros*, Greek = fire) and dimethylpyridine (lutidine; *lutum*, Latin = dirt) from bone oil [2].

Ramsay synthesized pyridine in 1876 by passing a mixture of acetylene and hydrogen cyanide through a red-hot tube [3]. Typical syntheses of pyridine derivatives are based on the work of Hantzsch (1882) [4] and Chichibabin (1906) [5]. The method of the latter is especially suitable for mass production and it is still an important industrial process.

Compounds containing a pyridine ring, such as vitamin B_6 (pyridoxine) [6], nicotinamide [7], nicotinic acid, the coenzymes nicotinamide adeninedinucleotide (NAD) and reduced NAD (NADH), and many alkaloids, play important roles in metabolism. Pyridine bases are widely used in pharmaceuticals including nicotinamide and nicotinic acid. Similarly, pyridine derivatives are important insecticides and herbicides due to their high bioactivity. Further, they are used as adhesives for textiles and as chemicals, solvents, and catalysts.

2. Pyridine and Alkylpyridines

Pyridine and alkylpyridines are produced commercially by synthesis as well as by isolation from natural sources such as coal tar. Commercially important compounds are pyridine, 2-methylpyridine, 3-methylpyridine, 4-methylpyridine, 2,6-dimethylpyridine, 3,5-dimethylpyridine, and 5-ethyl-2-methylpyridine.

2.1. Properties

Pyridine is miscible in all proportions with water and most common organic solvents and has a boiling point 35 °C higher than benzene.

Physical data of pyridine and alkylpyridines are summarized in Table 1.

Since the pyridine ring has three double bonds, six π-electrons exist, which are sufficient for aromatic ring formation without involving the lone pair electrons of the nitrogen atom. Since the lone pair electrons remains free, quaternary salts retain the aromaticity. However, the nitrogen atom has a higher electronegativity than the carbon atoms and shows an electron-withdrawing effect. This is represented by the resonance hybrids:

Therefore the electron densities at the 2- and 4-positions are low, and the ring is regarded as a

π-electron-deficient aromatic ring. The weak basicity of pyridine and alkylpyridines is due to the lone pair of electrons on the ring nitrogen atom. The basicity of pyridine derivatives is increased by electron-donating substituents and decreased by electron-withdrawing substituents.

In oxidation and reduction reactions, the pyridine ring exhibits properties characteristic of π-electron-deficient aromatic rings: resistance to oxidation and facile reduction. In the oxidation of alkylpyridines with alkaline $KMnO_4$, the pyridine ring is not oxidized; instead the corresponding carboxylic acids are formed [8]. Furthermore in the oxidation of quinoline with alkaline $KMnO_4$, the main product is pyridine-2,3-dicarboxylic acid. This shows that the pyridine ring is more stable to oxidation than the benzene ring [9].

On reduction with hydrogen in the presence of catalyst, quinoline and 2-phenylpyridine are reduced preferentially at the pyridine ring [10].

Because of the low π-electron density at the ring carbon atoms, electrophilic reactions rarely occur on the pyridine ring, and they occur at the 3-position only under drastic conditions. Although nitration of pyridine bases is difficult [11], sulfonation occurs more readily [12].

Friedel – Crafts reactions and reactions catalyzed by $PdCl_2$ such as oxychlorination of benzene, which are useful for benzene derivatives, do not take place because of the coordination of the nitrogen atom to $AlCl_3$ or $PdCl_2$. Electron-donating substituents such as hydroxyl, amino, or alkyl groups attached to the pyridine ring facilitate electrophilic reactions because of the increased electron density in the ring.

In contrast, nucleophilic substitution reactions occur readily at the 2-, 4-, and 6-positions. Treatment of pyridine with sodium amide gives 2-aminopyridine

(Chichibabin reaction) [13]. Reaction of pyridine bases with Grignard reagent, alkyllithium, or aryllithium gives 2-substituted pyridines [14]. Treatment of pyridine with methanol and hydrogen in the presence of a nickel catalyst gives 2-methylpyridine [15]. Substitution reactions of 2- or 4-halopyridines with nucleophiles, such as alkoxides, thiolates, amines, or carbanions, occur easily and provide important synthetic methods.

Radical reactions of pyridine – for example, the phenylation of pyridine with benzene diazonium chloride – give substituted products in the decreasing order 2- $>$ 3- $>$ 4- [16], and chlorination with chlorine above 270 °C or under UV irradiation gives a mixture of 2-, 4-, and 6- chloropyridines.

In the reaction of substituted groups in the pyridine ring, dealkylation and decarboxylation occur mainly at the 2-position [17], whereas hydroxymethylation of methyl groups with formaldehyde occurs at the 2- and 4-positions [18].

Like aliphatic tertiary amines, pyridine bases give *N*-oxides with hydrogen peroxide and peroxy acids, and form quaternary ammonium salts with alkyl halides.

2.2. Production

2.2.1. Separation from Tar

Pyridine bases are a constituent of tars. They were isolated from coal tar or coal gas before synthetic manufacturing processes became established. The amounts contained in coal tar and coal gas are small, and the pyridine bases isolated from them are a mixture of many components. Thus, with a few exceptions, isolation of pure pyridine bases was expensive. Today, almost all pyridine bases are produced by synthesis.

2.2.2. Synthesis from Aldehydes or Ketones with Ammonia

The reaction of aldehydes or ketones with ammonia is the most general synthetic reaction for the manufacture of pyridine bases and allows the preparation of various pyridines. This reaction was first studied in detail by CHICHIBABIN in 1924 [19] and since then been studied extensively for industrial manufacturing because of cheap access to raw materials. The reaction is usually carried out at 350 – 550 °C and a space velocity of 500 – 1000 h^{-1} in the presence of a solid acid catalyst (e.g., silica – alumina).

Aldehydes react with ammonia as follows:

For example, acetaldehyde and ammonia give 2-methylpyridine (Eq. 1) and 4-methylpyridine (Eq. 2). Some examples of the synthesis are given in Table 2.

With α, β-unsaturated aldehydes the reaction occurs according to the following schemes:

For example, acrolein and ammonia give 3-methylpyridine (Eq. 3); pyridine is simultaneously formed by demethylation. Examples of this synthesis are given in Table 3.

Acrolein and acetaldehyde react with ammonia mainly to form pyridine:

Acrolein and propionaldehyde react with ammonia to give primarily 3-methylpyridine (Eq. 5).

Acetaldehyde and formaldehyde react with ammonia to give mainly pyridine (Eq. 6): they appear to first form acrolein (Eq. 7), and then acrolein and formaldehyde react with ammonia to give pyridine. Simultaneously, 2-, 3-, and 4-methylpyridines are formed, as shown in Equations (1) – (4). This method is one of the most widely used for pyridine production. Table 4 lists some examples of this process, and Figure 1 illustrates the flow sheet of the plant.

A preheated gaseous mixture of acetaldehyde, 36 % formaldehyde, and ammonia is

passed through the reactor (a) packed with the catalyst at 400 – 450 °C. The reaction mixture is separated from ammonia and hydrogen by a collector (b) and extracted with solvent, e.g., benzene (c). The solvent is removed from the extract (d) and pyridine and 3-methylpyridine are isolated in continuous distillation columns (e). The catalyst is periodically regenerated by air.

(6)

$$CH_3CHO + HCHO \longrightarrow CH_2{=}CHCHO + H_2O \quad (7)$$

Propionaldehyde and formaldehyde react with ammonia to give 3,5-dimethylpyridine (Eq. 8) [31]; benzaldehyde and acetaldehyde give 2-phenylpyridine [*1008-89-5*] (Eq. 9) and 4-phenylpyridine [*939-23-1*] (Eq. 10) [32].

(8)

(9)

(10)

Ketones and aldehydes react with ammonia according to the following general scheme:

Typically, acetone [*67-64-1*] and formaldehyde with ammonia give 2,6-dimethylpyridine (Eq. 11) [33]:

(11)

α,β-Unsaturated ketones or aldehydes react with ammonia according to the following scheme:

For example, acrolein and acetone react with ammonia to give 2-methylpyridine (Eq. 12) [34]:

(12)

As a variant, acetone with ammonia gives 2,4,6-trimethylpyridine [*108-75-8*] with simultaneous demethylation (Eq. 13) [35]. Cyclopentanone [*120-92-3*] and acrolein with ammonia give 2,3-cyclopentenopyridine [*533-37-9*] (Eq. 14) [36]. Using aniline instead of ammonia results in formation of quinoline (Eq. 15):

(13)

(14)

(15)

As shown above, various pyridines can be obtained by using different combinations of aldehydes, ketones, ammonia, and amines.

2.2.3. Synthesis from Acrylonitrile and Ketones

Synthesis from acrylonitrile and acetone gives 2-methylpyridine selectively, in contrast to the process using acetaldehyde and ammonia, which gives 4-methylpyridine as a byproduct. First, the reaction of acrylonitrile and acetone, catalyzed by a primary aliphatic amine such

as isopropylamine and a weak acid such as benzoic acid [*65-85-0*], occurs in the liquid phase at 180 °C and 2.2 MPa to give 5-oxohexanenitrile [*10412-98-3*], with 91 % selectivity (Eq. 16). The acrylonitrile conversion is 86 % [37]. Then cyclization and dehydration of the initial product are carried out in the gas phase in the presence of hydrogen over a palladium, nickel, or cobalt-containing catalyst at ca. 240 °C to give 2-methylpyridine in 84 % yield (Eq. 17) [38]. 4-Methyl-5-oxohexanenitrile [*10413-01-1*], formed from acrylonitrile and 2-butanone, gives 2,3-dimethylpyridine [*583-61-9*] in 89 % yield [38].

2.2.4. Synthesis from Dinitriles

In a vapor-phase reaction over a nickel-containing catalyst in the presence of hydrogen, 2-methylglutaronitrile [*4553-62-2*] gives 3-methylpiperidine [*626-56-2*], which then undergoes dehydrogenation over palladium – alumina to give 3-methylpyridine [39]:

A one-step gas-phase reaction over a palladium-containing catalyst is reported to give 3-methylpyridine in 50 % yield [40].

2.2.5. Dealkylation of Alkylpyridines

Alkylpyridines of low commercial value, obtained as byproducts of pyridine base synthesis, are occasionally converted into useful pyridine bases by dealkylation. The methods for dealkylation involve oxidative dealkylation by air over a vanadium oxide catalyst [23], steam dealkylation over a nickel catalyst [24, 25], and hydrodealkylation over a silver or platinum catalyst [44]. Examples are listed in Table 5.

2.2.6. Synthesis of 5-Ethyl-2-Methylpyridine from Paraldehyde and Ammonia

Reaction of paraldehyde with aqueous ammonia in the liquid phase is carried out at 200 – 300 °C and 12 – 13 MPa in the presence of an ammonium salt (e.g., ammonium phosphate) to give 5-ethyl-2-methylpyridine (MEP) in about 70 % yield (Eq. 20) [45]. Figure 2 shows the reaction route, and Figure 3 illustrates the manufacture of MEP by the Montecatini – Edison process.

Paraldehyde, produced from acetaldehyde and sulfuric acid, is reacted with 30 – 40 % aqueous ammonia and acetic acid at 220 – 230 °C and 10 – 20 MPa. The reaction mixture is separated into two phases in a separator (c). Ammonia is recovered from the aqueous layer by a stripper (d). MEP, 2-methylpyridine, and 4-methylpyridine are isolated from the organic layer by distillation.

2.2.7. Synthesis from Nitriles and Acetylene

Liquid-phase reaction of nitriles with acetylene is carried out at 120 – 180 °C and 0.8 – 2.5 MPa in the presence of an organocobalt catalyst and gives 2-substituted pyridines [46]:

For example, acetonitrile [*75-05-8*] and acetylene react in the presence of cobaltocene as catalyst to give 2-methylpyridine in 76 % yield [47]. Acrylonitrile and acetylene react in the

presence of cyclopentadienylcobalt – cycloocta-1,5-diene catalyst to give 2-vinylpyridine with 93 % selectivity [48].

2.2.8. Other Synthetic Methods

Ethylene [*74-85-1*] and ammonia react in the presence of a palladium complex catalyst to give 2-methylpyridine and MEP [49]. Pyridine can be prepared from cyclopentadiene by ammoxidation [50], or from 2-pentenenitrile [*13284-42-9*] by cyclization and dehydrogenation [51]. Furfuryl alcohol or furfural reacts with ammonia in the gas phase to give pyridine [52]. 2-Methylpyridine is also prepared from aniline [53].

2.3. Quality Specifications, Storage, and Transportation

Specifications of pyridine vary according to country but are usually > 99.8 % purity by gas chromatographic analysis. Table 6 lists the standard specification for refined pyridine (ASTM) in the United States [54].

Table 6. Standard specifications of refined pyridine (ASTM) [54]

Appearance	clear liquid, free of extraneous matter and sediment
Odor	pyridine, characteristic
$d^{15.56}$	0.985 – 0.990
Color	not darker than no. 20 on platinum – cobalt scale
Distillation range at atmospheric pressure	
Total distillation range	$\leq 2\,^{\circ}C$
Initial distillation temperature (first drop)	$\geq 114.0\,^{\circ}C$
End point (dry point)	$\leq 117.0\,^{\circ}C$
Water	≤ 0.20 wt %
Water solubility	clear solution, no turbidity or oil film

Pyridine bases should generally be stored under dark, cool conditions. They are transported in drums, tank cars, and bulk containers in accordance with the following regulations:

Road:	GGVS/ADR	Class 3, No. 15 b
Rail:	GGVE/RID	Class 3, No. 15
Sea:	GGVSee/IMDG	Class 3.2
Air:		Class 3
	IATA-DGR	
UN no.:	1282	

2.4. Uses

Pyridine is an excellent solvent, especially for dehydrochlorination reactions and extraction of antibiotics. Large amounts of pyridine are used as starting material for pharmaceuticals and agrochemicals: for example, herbicides such as diquat and paraquat, insecticides such as chlorpyrifos, and fungicides such as pyrithione (see Section 3.12).

2-Methylpyridine. The major use of 2-methylpyridine is as a precursor of 2-vinylpyridine. The terpolymer of 2-vinylpyridine with butadiene and styrene is used as an adhesive for textile tire cord. 2-Methylpyridine is also used as a material for a variety of pharmaceuticals and agrochemicals: for example, chemicals such as nitrapyrin to prevent loss of ammonia from fertilizers, herbicides such as picloram, and coccidiostats such as amprolium (see Section 3.12).

3-Methylpyridine. A considerable amount of 3-methylpyridine is used as a starting material for pharmaceuticals and agrochemicals: for example, insecticides such as chlorpyrifos, feed additives such as nicotinic acid and nicotine carboxamide, and herbicides such as fluazifop-butyl (see Section 3.12).

4-Methylpyridine. The primary use of 4-methylpyridine is in the production of the antituberculosis agent isonicotinic hydrazide. Polymers containing 4-vinylpyridine, obtained from 4-methylpyridine, are used as anion exchangers (see Section 3.12).

Polyalkylpyridines. Large amounts of MEP are used as a starting material for nicotinic acid. 2,6-Dimethylpyridine is used for the antiarteriosclerotic pyridyl carbamate, while 3,5-dimethylpyridine is used for producing the antiulcer medication omeprazole (see Section 3.12).

2.5. Economic Aspects

The amounts of pyridine bases produced worldwide are estimated roughly as follows: pyridine, ca. 26 000 t/a (1989); 2-methylpyridine, ca. 8000 t/a (1989); 3-methylpyridine, ca. 9000 t/a

(1989); 4-methylpyridine, ca. 1500 t/a (1989); and MEP, ca. 8000 t/a (1989). Table 7 lists the primary manufacturers of pyridine and alkylpyridines.

3. Pyridine Derivatives

3.1. Vinylpyridines

Vinylpyridines have the following general formula:

2-Vinylpyridine was first synthesized in 1887, and 4-vinylpyridine in 1920. However, not until 1950 did vinylpyridines begin to be used for various commercial purposes. Only 2- and 4-vinylpyridines are of industrial importance; Table 8 lists some physical properties.

Due to the electron-withdrawing effect of the ring nitrogen atom, 2- and 4-vinylpyridines act as electrophiles. Nucleophiles such as methoxide, cyanide, hydrogen sulfide, and others add to 2- and 4-vinylpyridine at the vinylic site to give addition products. The reactions shown below have been carried out on a commercial scale [55–57]:

In addition to these Michael-type reactions, vinylpyridines are reduced at the side chain to give ethylpyridines [58]. Addition of chlorine to the vinyl group leads to (1,2-dichloroethyl)-pyridines [59].

Vinylpyridines are readily polymerized or copolymerized with styrene, butadiene, isobutylene, methyl methacrylate, and other compounds in the presence of radical, cationic, and anionic initiators. The homopolymer is soluble in organic solvents such as methanol and acetone, whereas cross-linked copolymers are insoluble in organic solvents.

Preparation. Industrially, 2- and 4-vinylpyridines are manufactured by treatment of 2- or 4-methylpyridine with aqueous formaldehyde, followed by dehydration of the resulting intermediate alcohol [60]:

For the manufacture of 2-vinylpyridine, the reaction is carried out at 150 – 200 °C in an au-

toclave. The conversion must be kept relatively low with short reaction time to suppress the formation of byproducts. After removal of unreacted 2-methylpyridine by distillation, concentrated aqueous sodium hydroxide is added to the residue and the resultant mixture is distilled under reduced pressure. During distillation, the dehydration of 2-(2-pyridyl)ethanol occurs to give 2-vinylpyridine as a distillate, which can be purified further by fractional distillation under reduced pressure in the presence of an inhibitor such as 4-*tert*-butylcatecohol. 4-Vinylpyridine is manufactured by a similar method.

Uses. Among vinylpyridines, only 2-vinylpyridine is in large demand, as much as 3000 t annually. The polymer of 2-methyl-5-vinylpyridine [*140-76-1*] was formerly used as a coating material for medicine tablets; today, it is not used at all. Although 4-vinylpyridine has been used for various purposes, its total annual demand is presumed to be only several hundred tons.

Most of the 2-vinylpyridine is used in the production of a latex terpolymer of 2-vinylpyridine, styrene, and butadiene, used as a tire-cord binder.

The cross-linked resin made from 4-vinylpyridine and divinylbenzene has been used to remove poisonous hexavalent chromium ions from wastewater [61] by formation of complexes with the nitrogen atoms of the pendant pyridine rings. Similarly, this type of resin can be used to remove or recover phenol from wastewater [62]. Furthermore, the poly(4-vinylpyridines) are used as ion-exchange membranes and electrodes for reversible cells.

The addition product of methanol to 2-vinylpyridine, 2-(2-methoxyethyl)pyridine is a veterinary anthelmintic (methypidine) [63]. 4,4′-(1,3-Propanediyl)bispiperidine, made from 4-vinylpyridine, is used as a raw material for polyamide resins [64], and 2-(4-pyridyl)ethylsulfonic acid from 4-vinylpyridine is a coagulation accelerator for the gelatin layer of photographic plates [65].

3.2. Bipyridines

Bipyridines have become increasingly important as intermediates for herbicides since the 1960s. A significant part of pyridine is used for the manufacture of bipyridines (i.e., 2,2′- and 4,4′-bipyridine). The herbicides diquat [*85-00-7*] and paraquat (dichloride [*1910-42-5*]; bis(methylsulfate) [*2074-50-2*]) are produced by quaternization of 2,2′- and 4,4′-bipyridines, respectively. Their physical properties are listed in Table 9.

2,2′-Bipyridine is synthesized by the dimerization of pyridine in the presence of an oxidizing agent or catalyst, such as iron(III) chloride, iodine, or nickel – aluminum, or by the reaction of 2-bromopyridine with copper. For industrial production, Raney nickel is used, and the amount of catalyst employed is an indicator of the economy of the process. In Table 10, the historical development of the process is demonstrated in terms of the decrease in amount of catalyst employed.

Table 10. Amount of Raney nickel employed in synthesis of 2,2′-bipyridine

Production of 4,4′-Bipyridine. As early as 1870, pyridine was known to react with sodium to give 4,4′-bipyridine after oxidation of the initial product [72]. The reduction of pyridine with zinc powder and acetic acid followed by oxidation was also known. Many patents have been applied for concerning the improvement of this procedure with respect to reaction temperature, choice of solvent, and isolation of the product. The ICI process, which seems at present to be the best, is described below [73].

Sodium is dissolved in liquid ammonia at −45 °C, and the solution is successively diluted with pyridine and *N,N*-dimethylformamide. The resulting mixture is poured into *N,N*-dimethylformamide at −25 °C, while air is passed through the solution. The mixture is then warmed to room temperature, and ammonia is allowed to evaporate. After work-up, 4,4′-bipyridine is obtained in 84 % yield.

Other variants are described in [74–77].

Table 9. Physical properties of bipyridines (M_r 156.18)

Compound	CAS registry no.	*mp*, °C	*bp*, °C	Solubility in water
2,2′-Bipyridine	[*366-18-7*]	70.1	272 – 273	sparingly soluble
2,3′-Bipyridine	[*581-50-0*]		295 – 296	practically insoluble
2,4′-Bipyridine	[*581-47-5*]	61.1 – 61.5	280 – 282	practically insoluble
3,3′-Bipyridine	[*581-46-4*]	68	291 – 292	readily soluble
3,4′-Bipyridine	[*4394-11-0*]	61	297	soluble in hot water
4,4′-Bipyridine	[*553-26-4*]	114	304.8	soluble in hot water

3.3. Quaternary Pyridinium Salts

Properties. Pyridine and some of its derivatives are readily converted to quaternary salts by alkylating agents such as alkyl halides. Quaternary salts can be regarded as being formed by the neutralization of strong bases (i.e., pyridinium hydroxides) with strong acids (e.g., hydrogen halides). Therefore, these salts are practically neutral when dissolved in water. Although stable under normal conditions, they are degraded into pyridine hydrohalides and alkenes on intense heating [78], or they undergo the Ladenburg rearrangement in the presence of copper as a catalyst [79]:

The pyridine ring of these salts is susceptible to nucleophilic attack as a result of the quaterniza-tion of the nitrogen atom. The reaction of 1-methylpyridinium salts with alkaline ferricyanide gives *N*-methylpyridone via oxidation of a pseudobase, which is considered to exist at low concentration in equilibrium with the pyridinium hydroxide [80, 81]:

1-Pyridylpyridinium dichloride [*5421-92-1*], obtained from pyridine and thionyl chloride or chlorine, is particularly useful as a synthetic intermediate [82, 83]. It affords 4-amino- and 4-hydroxypyridine on ammonolysis and hydrolysis, respectively. Treatment with phenol and sodium phenoxide gives 4-phenoxypyridine, and reaction with hydrogen sulfide in pyridine gives 4-mercaptopyridine [84–87].

Uses. The major use of quaternary pyridinium salts is in the manufacture of the herbicides paraquat and diquat. These compounds are produced by the quaternization of 4,4′-bipyridyl and 2,2′-bipyridyl with methyl chloride and dibromoethane, respectively. Higher alkylpyridinium salts are used in the textile industry as dye auxiliaries and spin bath additives (antistatic agents and softeners). The higher alkylpyridinium salts also exhibit antimicrobial activity. Hexadecylpyridinium chloride [*123-03-5*] is a topical antiseptic, and amprolium [*121-25-5*], a quaternary salt of 2-methylpyridine, is a veterinary coccidiostat.

Hexadecylpyridinium chloride

Amprolium

Of the many quaternary salts, 1-butylpyridinium bromide [*1124-64-7*] and other lower 1-

alkyl homologues are of interest. Although each component is solid at ambient temperature, the mixture of these salts with aluminum chloride leads to melts that can exist as liquids below room temperature in fairly wide proportions.

The molten salt with $n = 2$ exhibits a specific conductivity of ca. 7 mS/cm at 25 °C [88]. The utilization of these molten salts for battery electrolytes [89] and electroplating baths for aluminum has been proposed [90]. These binary salts are reportedly excellent solvents and catalysts for Friedel–Crafts reactions [91] and for the formylation of toluene by carbon monoxide [92].

3.4. Pyridine *N*-Oxides

Properties. Some physical properties of pyridine *N*-oxides are listed in Table 11.

Resonance structures of pyridine *N*-oxide are as follows:

The *N*-oxide group in pyridine *N*-oxide has both electron-withdrawing and electron-donating effects. Consequently, pyridine *N*-oxide reacts with both electrophiles and nucleophiles, resulting in a more versatile reactivity of the pyridine ring compared to pyridine itself.

Nitration of pyridine *N*-oxide is a typical electrophilic reaction of the *N*-oxide. Pyridine *N*-oxide is nitrated under relatively mild conditions due to the contribution of structures **1** and **2**, giving 4-nitropyridine *N*-oxide in good yield [93, 94], in contrast to the nitration of pyridine, which requires drastic conditions and gives 3-nitropyridine only in poor yield. The nitro group of 4-nitropyridine *N*-oxide can be reduced to an amino group or displaced by various nucleophiles such as halides and alkoxides to give many useful 4-substituted pyridines. The oxygen of pyridine *N*-oxides can usually be removed by phosphorus trichloride.

Owing to the contribution of resonance structures **3** and **4**, the oxygen atom of the *N*-oxide group readily undergoes protonation, acylation, allylation, etc. Reaction with nucleophiles proceeds via quaternized intermediates, an example being the formation of 2-acetoxypyridine [*3847-19-6*] from the reaction of pyridine *N*-oxide with acetic anhydride [95]:

Trimethylsilyl cyanide, formed in situ from trimethylsilyl chloride and sodium cyanide, reacts with pyridine *N*-oxide to give almost exclusively 2-pyridinecarbonitrile [*100-70-9*] in 80 % yield [96]. Although the chlorination of pyridine *N*-oxide with sulfuryl chloride gives a mixture of 2- [*109-09-1*] and 4- chloropyridines [*626-61-9*] [97], treatment of 3-methylpyridine *N*-oxide with phosphoryl chloride in the presence of diisopropylamine yields predominantly 2- chloro-5-methylpyridine [*18368-64-4*] [98]. In the chlorination of 3-pyridinecarbonitrile *N*-oxide and nicotinic acid *N*-oxide, 2- chloro-3-pyridinecarbonitrile [*6602-54-6*] [99] and 2-chloronicotinic acid [*2942-59-8*] [100] are obtained as the main products.

The *N*-oxide of 2-methylpyridine reacts with acetic anhydride at the methyl group to give 2-acetoxymethylpyridine [*1007-49-4*] [101], which on hydrolysis leads to 2-pyridylmethanol [*586-98-1*].

Preparation. Pyridine *N*-oxide can be prepared by treatment of pyridine with 30 % hydrogen peroxide in acetic acid [102]. A similar and easier method is also known [103], in which molybdenum trioxide is used as catalyst and water as solvent. Pyridine *N*-oxide and its alkyl derivatives are isolated by distillation after complete decomposition of unreacted peroxides.

Table 11. Physical properties of pyridine N-oxides

Compound	CAS registry no.	*mp*, °C	*bp*, °C (kPa)	pK_a
Pyridine *N*-oxide	[*694-59-7*]	67	122 – 124 (0.67)	0.79 (24 °C)
2-Methylpyridine *N*-oxide	[*931-19-1*]		123 – 124 (2.0)	
3-Methylpyridine *N*-oxide	[*1003-73-2*]	37 – 38	146 – 149 (2.0)	1.08 (25°C)
4-Methylpyridine *N*-oxide	[*1003-67-4*]	186 – 188		1.29 (25°C)
Nicotinic acid *N*-oxide	[*2398-81-4*]	258		
3-Pyridinecarbonitrile *N*-oxide	[*14906-64-0*]	178		

Uses. Pyridine *N*-oxides are important as synthetic intermediates in the manufacture of pharmaceuticals and agrochemicals. The antiulcer agent omeprazole [*73590-58-6*] is produced from 2,3,5-trimethylpyridine *N*-oxide [*74409-42-0*]. Niflumic acid [*4394-00-7*] and pranoprofen [*52549-17-4*] are analgesics and anti-inflammatories, which are manufactured from nicotinic acid *N*-oxide, obtained either by *N*-oxidation of nicotinic acid or by hydrolysis of 3-pyridinecarbonitrile *N*-oxide. Zinc pyrithione [*13463-41-7*], the zinc salt of 2-pyridinethiol *N*-oxide [*1121-31-9*], is a fungicide derived from 2- chloropyridine *N*-oxide [*2402-95-1*].

3.5. Piperidines (see also → Amines, Aliphatic)

Physical properties of common piperidines are listed in Table 12.

Piperidines react with alkyl halides and acid anhydrides to give *N*-alkylpiperidines and amides, respectively.

Piperidine and most of its derivatives are easily produced by hydrogenation of the corresponding pyridine derivatives at elevated temperature and pressure over nickel, palladium, or ruthenium catalysts [104–108].

A major use of piperidine is in the production of dithiuram tetrasulfide [*120-54-7*], which is used as a vulcanization accelerator in the rubber industry. Other uses of piperidine are in the production of vasodilators such as dipyridamole and minoxidil , diuretics such as etozolin , and fungicides such as piperalin . Piperidine is also used as a solvent. 2-Methylpiperidine is used for the herbicide piperophos , and *cis*-2,6-dimethylpiperidine for the antiarrhythmic pirmenol . 4-Benzylpyridine is quaternized and hydrogenated to give a 4-benzylpiperidine derivative that is used as a cerebral vasodilator (ifenprodil tartrate) .

3.6. Halopyridines

Physical properties of common halopyridines are listed in Table 13.

The 2- and 4- chloropyridines react with various nucleophiles to give alkyl ether [109], alkyl thioether [110], and alkylamine derivatives [111]. Furthermore, pyridylation of phenylacetonitrile can be achieved by using strong base [112].

Because of its relatively low reactivity, 3-chloropyridine does not undergo nucleophilic attack easily.

Haloalkylpyridines are useful intermediates for pyridylacetonitriles [113] or benzimidazolylthiomethylpyridines [114, 115].

Table 12. Physical properties of piperidines

Halogenation of pyridines generally gives a mixture of chlorinated pyridines. For instance, direct chlorination of pyridine with molecular chlorine can be achieved above 270 °C to give 2-chloropyridine and 2,6-dichloropyridine [116–118].

In the chlorination of methylpyridines, reaction occurs first at the side chain and then at a

ring position. Liquid-phase chlorination generally leads to chloromethylpyridines [119].

In contrast, gas-phase chlorination tends to give a mixture of trichloromethylchloropyridines [120–122]:

Exhaustive chlorination of pyridines gives pentachloropyridine [123, 124]:

Pentachloropyridine can be reduced by zinc metal to 2,3,5,6-tetrachloropyridine because of enhanced reactivity at the 4-position [125, 126].

5-Trifluoromethyl-2- chloropyridine is produced directly from 3-methylpyridine by the combined action of chlorine and hydrogen fluoride [127]:

The preparation of 2- and 4- chloropyridines from pyridinols is achieved by the use of halogenating reagents such as phosphoryl chloride [128–130].

Pyridyl alcohols react with thionyl chloride or phosphorus halide reagents, such as phosphoryl chloride, phosphorus trihalide, or phosphorus pentahalide, to give the corresponding haloalkylpyridines [114, 115, 131].

Diazotization of aminopyridines in the presence of halide ions is used for the preparation of halopyridines [132–135].

Chlorination of pyridine *N*-oxides leads to halopyridines; usually, 2- and 4-isomers are formed by the action of phosphorus halide reagents [98–100] (see Section 3.4):

In industry, vapor-phase chlorination products are important intermediates for pharmaceuticals and agrochemicals.

A major use of 2- chloropyridine is the production of pyrithione, which is used widely as a fungicide. Another use is in the production of insecticides such as pyripropoxyfen. Pyridylation products of phenylacetonitrile lead to antihistamines such as chloropheniramine and antiarrhythmics such as disopyramide . Reaction of 4-chloropyridine with mercaptoacetic acid gives pyridylmercaptoacetic acid, which is a precursor for cephalosporin antibiotics (e.g., cephapirin sodium salt) . 2,6-Dichloropyridine is used for quinoline antibiotics such as enoxacin.

2-Chloro-6-trichloromethylpyridine is used to prepare nitrapyrin, which prevents the loss of ammonia from fertilizers. 2,5-Dichloro-6-trichloromethylpyridine is converted to the herbicide clopyralid . 2,3,4,5-Tetrachloro-6-trichloromethylpyridine is a precursor of the herbicide picloram . 2,3,5,6-Tetrachloropyridine is used for producing the insecticide chlorpyrifos, and 2- chloro-5-trifluoromethylpyridine for the herbicide fluazifop-butyl .

Uses of liquid-phase chlorination products are limited at present. Major uses of 2-chloropyridine-3- carboxylic acid are for the production of herbicides such as diflufenican

and anti-inflammatory agents such as niflumic acid and pranoprofen.

3.7. Pyridinecarbonitriles, Carboxylic Acids, and Carboxamides

The 3-carbonitrile, 3-carboxylic acid, and 3-carboxamide are important from both a physiological and an industrial point of view.

3-Pyridinecarboxylic acid and 3-pyridinecarboxamide are known as niacin. Niacin is widely distributed in plants and animals. It forms coenzymes, nicotinamide – adenine dinucleotide (NAD) and nicotinamide – adenine dinucleotide phosphate (NADP), which participate in oxidation – reduction cycles in living cells. Since 3-pyridinecarboxylic acid is obtained by oxidation of nicotine with nitric acid, it is commonly called nicotinic acid. 3-Pyridinecarbonitrile and 3-pyridinecarboxamide are referred to as nicotinonitrile and nicotinamide. The prefix isonicotin- is often used to denote the 4-position of pyridinecarbonitrile, - carboxylic acid, and - carboxamide.

Physical data for pyridinecarbonitriles, pyridinecarboxylic acids, and pyridinecarboxamides are listed in Table 14.

Pyridinecarbonitriles. Pyridinecarbonitriles are important intermediates for a variety of pyridine derivatives [136–141]:

Pyridinecarbonitriles are usually manufactured by catalytic vapor-phase ammoxidation of alkylpyridines :

Generally, 1 to 20 mol of ammonia and 2 to 20 mol of oxygen are used per mole of alkylpyridine. Reaction temperatures range between 280 and 500 °C. Catalysts containing vanadium oxide are commonly used. Examples of the process are given in Table 15, and a flow sheet is illustrated in Figure 4.

3-Methylpyridine is ammoxidized to 3-cyanopyridine in the reactor (a). The reaction gas is quenched with water in the absorber (b), and the condensed mixture is extracted with a solvent in the extraction column (c). 3-Cyanopyridine is separated from the solvent and 3-methylpyridine by three-stage distillation.

3-Pyridinecarbonitrile is used for the production of 3-pyridinecarboxamide (vitamin complex), and 4-pyridinecarbonitrile for antituberculosis agents such as isoniazid [148].

Pyridinecarboxylic Acids. Pyridinecarboxylic acids behave like ordinary carboxylic acids. Some important reactions are shown below [149, 150]:

Two basic methods are used for the production of pyridinecarboxylic acids: hydrolysis of pyridinecarbonitriles and nitric acid oxidation of alkylpyridines.

Pyridinecarbonitriles are hydrolyzed to pyridinecarboxamides under basic conditions at 0 – 100 °C; subsequent hydrolysis to pyridinecarboxylic acids is carried out under more severe conditions [151, 152].

Figure 4. Ammoxidation of 3-methylpyridine
a) Multitubular reactor; b) Absorber; c) Extraction column; d) Fractionating columns; e) Treatment of process water

Nitric acid oxidation of alkylpyridines (e.g., 5-ethyl-2-methylpyridine to 3-pyridinecarboxylic acid) has been developed commercially by Lonza.

The flow diagram of the process is shown in Figure 5 [153]. 5-Ethyl-2-methylpyridine (MEP) is mixed with nitric acid and fed to a tubular reactor (b). The reaction to form 3-pyridine carboxylic acid nitrate is carried out at 180–370 °C and 2–50 MPa. Nitrogen oxides gases are recovered by the absorber (d) and recycled. After removal of water (e), crystallization of the nitrate (f), and neutralization with MEP (i), the free acid is crystallized (j) and dried. Unreacted nitric acid from the separators (g, k) is recycled to the reactor.

3-Pyridinecarboxylic acid has been used mainly as vitamin B_3 or vitamin PP for treating pellagra. Furthermore, it is used as an intermediate for the vasodilator nicorandil . Other uses are for plant growth regulators (inabenfide); antihistamines (terfenadine) ; and antidepressants (nialamide) . 2-Piperidinecarboxylic acid, derived from 2-pyridinecarboxylic acid, is used as intermediate for local anesthetics such as mepivacaine hydrochloride and bupivacaine hydrochloride . 2,3-Pyridinedicarboxylic acid is used as an intermediate for the herbicide imazapyr .

Pyridinecarboxamides. Pyridinecarboxamides are used for the production of pyridinecarboxylic acids [152] and aminopyridines [154].

Pyridinecarboxamides are prepared by hydrolysis of pyridinecarbonitriles (see p. 415) [155].

3-Pyridinecarboxamide and 3-pyridinecarboxylic acid are important as vitamin B_3 [156]. 4-Pyridinecarboxamide is used for producing antibiotics (e.g., cefsulodin sodium) [157].

3.8. Aminopyridines

Table 16 lists commercially available aminopyridines and their physical properties.

3.8.1. 2-Aminopyridine

2-Aminopyridine [*504-29-0*] exists as tautomeric amino and imino forms. The amino form predominates over the imino form, and their ratio is generally 1000: 1.

2-Aminopyridine generally reacts with alkylating agents at the ring nitrogen to give derivatives of type **5**. In the presence of sodium amide or sodium methoxide, however, it reacts with alkylating agents at the exocyclic nitrogen. Such reactions are used to produce antihistamines of type **6**.

5 **6**

Electrophilic reactions such as halogenation and nitration occur at the positions *para* and *ortho* to the amino group [158–160]:

Figure 5. Lonza process for 3-pyridinecarboxylic acid

2-Pyridinol	[*142-08-5*]	95.10	280 – 281	105 – 107
3-Pyridinol	[*109-00-2*]	95.10	151 – 153 (0.4)	126 – 129
4-Pyridinol	[*626-64-2*]	95.10	230 – 235 (1.6)	146 – 149
6-Methyl-2-pyridinol	[*3279-76-3*]	109.13		158 – 160
6-Methyl-3-pyridinol	[*1121-78-4*]	109.13		168 – 170
5-Chloro-2-pyridinol	[*4214-79-3*]	129.55		163 – 165
2-Nitro-3-pyridinol	[*15128-82-2*]	140.10		69 – 71

The most important method for the manufacture of 2-aminopyridine is the reaction of pyridine with sodium amide (Chichibabin amination). Upon hydrolysis of the intermediate sodium salt, 2-aminopyridine is obtained in high yield [161–164]:

The major uses of 2-aminopyridine are as an intermediate for pharmaceuticals such as sulfapyridine [*144-83-2*], tripelennamine [*91-81-6*], piroxicam [*36322-90-4*], and tenoxicam [*59804-37-4*], as well as a variety of agrochemicals.

3.8.2. Other Aminopyridines

2-Amino-6-methylpyridine. 2-Amino-6-methylpyridine [*1824-81-3*] is produced from 2-methylpyridine and sodium amide. It is converted to nalidixic acid [*389-08-2*], an antibacterial agent [165].

2,6-Diaminopyridine. Amination of pyridine or 2-aminopyridine under severe conditions gives 2,6-diaminopyridine [*141-86-6*], the coupling of which with benzenediazonium salts gives the antiseptic phenazopyridine [*136-40-3*] [166]. 2,6-Diaminopyridine is also utilized for the production of polyamides.

3-Aminopyridine and 4-Aminopyridine. 3-Aminopyridine [*462-08-8*] and 4-aminopyridine [*504-24-5*] are produced from the corresponding pyridinecarboxamides and sodium hypochlorite in alkaline solution (Hofmann reaction).

These aminopyridines are used as intermediates for pharmaceuticals such as pinacidil [*85371-64-8*] and for agrochemicals.

***N,N*-Dimethyl-4-pyridinamine** [*1122-58-3*] is widely employed as a supernucleophilic catalyst for many organic reactions. Two processes are used for its production:

1) *N*-(4-Pyridyl)pyridinium halide, prepared from pyridine and halogenating agents, is reacted with dimethylamine or *N,N*-dimethylformamide to give *N,N*-dimethyl-4-pyridinamine [167–170].

2) 1-[2-(2-Pyridyl)ethyl]-4- cyanopyridinium chloride, prepared from 4-pyridinecarbonitrile, 2-vinylpyridine, and hydrogen halide, gives *N,N*-dimethyl-4-pyridinamine by a reaction similar to that described above [171].

The major uses are as a catalyst for acylation, alkylation, halogenation, cyanation, and silylation, and as an accelerator in the manufacture of polyurethanes.

3.9. Pyridinols

Physical properties of typical pyridinols are listed in Table 17.

Tautomerization of pyridinols is discussed in [172]; both 2- and 4-pyridiols prefer the ketonic pyridone tautomer to the hydroxylic tautomer.

In contrast, 3-pyridinol is a phenolic compound because the ketonic tautomer does not exist.

Chlorination of 2- and 4-pyridinols with phosphorus halides gives halopyridines [126–128].

Electrophilic substitution of pyridinols is facile because of the electron-donating nature of the hydroxyl group. Reaction occurs at positions *ortho* or *para* to the hydroxyl group, similar to phenols [173–176].

When 2- and 4-pyridinols are alkylated with alkyl halides, they give a mixture of the *O*- and *N*-alkylated products [177], but 3-pyridinol gives only the *O*-alkylated product [178].

Diazotization of aminopyridines is used for the production of pyridinols [179–182].

2-Pyridinol is also obtained from pyridine *N*-oxide by reaction with acid anhydrides and subsequent hydrolysis [183, 184].

2-Alkyl-3-pyridinols are reported to be formed from alkanoylfurans and ammonia under pressure [185–187].

2-Pyridinol is a synthetic intermediate for the tranquilizer amphenidone . 3-Pyridinol is used for synthesizing the cholinesterase inhibitors pyridostigmine bromide and distigmine bromide . 4-Pyridinol is a precursor of the X-ray contrast agent propyliodone. It is hydrogenated to give 4-piperidinol, which is used to produce the psychotropic agent pericyazine.

3.10. Pyridyl Alcohols

Physical properties of common pyridyl alcohols are listed in Table 18.

Reactivities of pyridyl alcohols are similar to ordinary alcohols; for example, chloroalkylpyridines are formed by the action of thionyl chloride or phosphorus halide reagents [130, 131], and dehydration gives alkenylpyridines.

Pyridylmethanols. The simple pyridylmethanols are produced by catalytic hydrogenation of pyridinecarbonitriles in acidic media [188].

Table 18. Physical properties of pyridyl alcohols

Compound	CAS registry no.	M_r	*bp*, °C (kPa)	*mp*, °C	n_D^{20}	d_4^{20}	Flash point, °C
2-Pyridylmethanol	[*586-98-1*]	109.13	112 – 113 (0.5)		1.5440	1.131	110
3-Pyridylmethanol	[*100-55-0*]	109.13	154 (2.9)		1.5460	1.124	130
4-Pyridylmethanol	[*586-95-8*]	109.13	107 – 110 (0.1)	57 – 59			112
2,6-Pyridyldimethanol	[*1195-59-1*]	139.15	185 (2.0)	114 – 116			
2-(2-Pyridyl)ethanol	[*103-74-2*]	123.16	114 – 116 (1.2)		1.5370	1.093	92
2-(4-Pyridyl)ethanol	[*5344-27-4*]	123.16	262				160

Substituted 2-pyridylmethanols can be produced from 2-methylpyridine *N*-oxides by the action of acetic anhydride, followed by hydrolysis [130, 131, 189].

2-Pyridylmethanol is used in the preparation of the anti-inflammatory ibuprofen piconol . 3-Pyridylmethanol is used as an intermediate for the vasodilator nicotinic alcohol. 2,6-Pyridyldimethanol is carbamated to give the antiarteriosclerotic agent pyridinol carbamate.

Pyridylethanols. Condensation of 2- or 4-methylpyridines with formaldehyde or other aliphatic aldehydes gives the corresponding pyridylethanols due to the high acidity of the methyl group in the 2- or 4-position [18, 190–193].

Pyridylethanols are used mainly for the manufacture of vinylpyridines (see Section 3.1). Other uses of 2-(2-pyridyl)ethanol are in the production of a psychotropic agent thioridazine and the antispasmodic tiquizium bromide .

3.11. Pyridinecarbaldehydes

Physical properties of typical pyridinecarbaldehydes are listed in Table 19.

Reactions of pyridinecarbaldehydes are similar to those of aromatic aldehydes: benzoin condensation [194], oxidation to pyridinecarboxylic acids [195], reduction to pyridylmethanols [196], oximation [197], and hydrazone formation [198].

Pyridinecarbaldehydes are prepared from pyridylmethanols by oxidation with manganese dioxide [199].

The oxidation of methylpyridines with selenium dioxide gives pyridinecarbaldehydes [200], which are also obtained by vapor-phase oxidation of methylpyridines over avanadium – molybdenum – titanium oxide catalyst [201].

Table 19. Physical properties of pyridylcarbaldehydes

Compound	CAS registry no.	M_r	*bp*, °C (kPa)	*mp*, °C	n_D^{20}	d_4^{20}	Flash point, °C
2-Pyridinecarbaldehyde	[*1121-60-4*]	107.11	181		1.5370	1.126	54
3-Pyridinecarbaldehyde	[*500-22-1*]	107.11	95 – 97 (0.9)		1.5490	1.135	60
4-Pyridinecarbaldehyde	[*872-85-5*]	107.11	77 – 78 (1.6)		1.5440	1.122	54
2-Pyridine aldoxime	[*873-69-8*]	122.13		110 – 112			
3-Pyridine aldoxime	[*1193-92-6*]	122.13		150 – 153			
4-Pyridine aldoxime	[*696-54-8*]	122.13		130 – 133			

The catalytic partial reduction of 3-pyridinecarbonitrile with hydrogen over a palladium catalyst in acidic media gives 3-pyridinecarbaldehyde [202].

Quaternary salts of pyridinecarbaldehyde oximes, particularly pralidoxime methiodide, are used as antidotes for poisoning by organophosphate acetylcholinesterase inhibitors. Another use of 2-pyridinecarbaldehyde is in the production of bisacodyl , a laxative.

3.12. Pharmaceuticals and Agrochemicals

Typical pharmaceuticals and agrochemicals derived from pyridine are listed in Table 20.

4. Toxicology

4.1. Acute Toxicity

The acute toxicity of pyridine and its common derivatives is listed in Table 21.

Pyridine has a narcotic action. Toxic doses cause weakness, ataxia, unconsciousness, and salivation. In humans, pyridine is readily absorbed through the lungs, gastrointestinal tract, and skin. In 1893 a human fatality resulted from the accidental ingestion of half a cupful of commercial pyridine [203]. OSHA states that a vapor concentration of 3600 ppm in air is immediately dangerous to life and health [204]. The LDLo (oral) in humans is 500 mg/kg [205].

The acute toxicity of monoalkylpyridines is similar to that of pyridine, but some dimethyl- and trimethylpyridines are several times more toxic than pyridine. 2-Methylpyridine is one of the most important commercially produced alkylpyridines; its toxicity and safety data are summarized in [206].

Of aminopyridines, the toxicity of 4-aminopyridine has been thoroughly investigated because of its high toxicity and its use as a bird repellent. The acute toxicity of 4-aminopyridine has been determined for 41 species of birds and mammals. The oral LD_{50} values are generally < 10 mg/kg [207], and the LDLo (oral) in humans is 0.59 mg/kg. Most of the pharmacological effects of 4-aminopyridine can be attributed to its neurotoxicity [208].

The calculated fatal dose of 2-aminopyridine for a man of 70-kg weight is ca. 5 g [209]. A fatal accident involving 2-aminopyridine was described as follows: an employee died 1.5 h after spilling 2-aminopyridine on his clothes during its distillation and continuing to work. Aminopyridines are toxic if inhaled, swallowed, or absorbed through skin [209].

The acute toxicity of 13 chlorinated pyridines has been investigated [210], including monochloro to pentachloro derivatives. In the comparison of relative toxicity to mice by intraperitoneal injection, 2,6-dichloropyridine shows the highest toxicity ($LD_{50} = 115$ mg/kg) and 2,5-dichloropyridine the lowest ($LD_{50} = 1690$ mg/kg).

The toxicity of 2-chloropyridine to rabbits after dermal application ($LD_{50} = 64$ mg/kg) and by intraperitoneal injection ($LD_{50} = 48$ mg/kg) indicates that 2-chloropyridine is readily absorbed through the skin.

∗ R = rat; M = mouse; Q = quail; Hum = human.

3-Acetylpyridine causes central neurotoxic effects upon intraperitoneal injection of 70–80 mg/kg in rats [211]. The zinc salt of 1-hydroxypyridine-2-thione (HPT), known as zinc pyrithione (ZnPT), is used as an antidandruff agent. The oral LD_{50} of HPT in mice is 533 mg/kg. The metal complexes (Zn, Cd) are more toxic than HPT itself. Percutaneous and eye toxicity is also discussed in [212].

Paraquat (1,1′-dimethyl-4,4′-bipyridinium dichloride), which consumes the largest amount of pyridine as starting material, exhibits very high toxicity. The oral LDLo in humans is 43 mg/kg. Nicotine is one of the well-known pyridine derivatives from natural sources, and its toxicity has been investigated in detail. The LDLo in humans is 0.882 mg/kg. Reports on the toxicity of paraquat and nicotine can be found in [213].

Vinylpyridines irritate the skin intensely, and contact with the vapor or liquid generally causes inflammation or blisters. They also show high toxicity by inhalation.

4.2. Subacute and Chronic Toxicity

Few long-term studies can be found on the toxicity of pyridine to animals. Six rats were fed a basal diet containing 0.1 % pyridine. Five rats died during the 14th to 32nd days. The livers and kidneys revealed acute lesions and some of the livers exhibited pronounced cirrhosis [214].

When humans are exposed to pyridine vapor, the toxicity affects mainly the central nervous system and the gastrointestinal tract. Symptoms are headache, dizziness, nausea, insomnia, anorexia, and weakness of the limbs. As examples, the cases of a chemist who had worked with pyridine for six months and of a man who had worked with it for 13 years are reported in [215]. Formerly, pyridine was used as an anticonvulsant, and an epileptic who received 1.8–2.5 mL/d of pyridine for one month died as a result of liver and kidney damage [216].

In 1983 Langston first reported that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes acute symptoms of parkinsonism [217]; more than 1000 papers have been published, mainly in the United States, in the following years [218].

4.3. Mutagenicity and Ecotoxicity

Mutagenic pyridine derivatives include 2,2′-bipyridine, 4-nitropyridine *N*-oxide derivatives, chloropyridine derivatives,chloromethylpyridine derivatives, 2,6-diaminopyridine, 4-phenylpyridine, 2-hydroxy-3-nitropyridine, isonicotinic acid hydrazide, and 2-pyridine aldoxime.

Of these compounds, chloromethylpyridine derivatives [219] and 4-nitropyridine *N*-oxide derivatives [220] have been investigated with respect to their carcinogenicity.

Pyridine has a characteristic disagreeable, nauseating odor, detectable at < 1 ppm. The odor threshold is 0.021 ppm [221]. TLV and MAK values (in ppm) in several countries are as follows:

Australia	5
Germany	5
Italy	2
Japan	5
CIS	1.7
United States	5

The acute toxicity of pyridine for *Daphnia magna* is 240 mg/L, and the 24-h LC_{50} is 170 mg/L for newborns and 944 mg/L for adults. Reported acute toxic concentrations in fish vary widely and range from 26 to 1300 mg/L [204].

1. Introduction

Pyrimidine was first isolated by GABRIEL and COLMAN in 1899 [1–4].

Pyrimidine [*289-95-2*], $C_4H_4N_2$, M_r 80.09, *mp* 20 – 22 °C, *bp* 123 – 124 °C, UV max (water): 240 nm (ε 2400) is a hygroscopic, water-soluble solid with a penetrating odor. It is also a weak base ($pK_a = 1.23$) that forms a number of solid derivatives (hydrochloride: *mp* 162 °C; picrate: yellow needles, *mp* 156 °C; methiodide: yellow plates, *mp* 136 – 137 °C). There are many synthetic approaches to the preparation of pyrimidine [4]. The most effective way to prepare pyrimidine in large quantity is to react 1,1,3,3-tetraethoxypropane with formamide over alumina at 200 °C [5].

2. Chemical Properties

The reactivity of the pyrimidine ring is approximately equivalent to that of 1,3-dinitrobenzene or 3-nitropyridine. This is because a double-bonded ring nitrogen is comparable in its electron-withdrawing ability to a nitro group.

Electrophilic substitution at the ring positions occurs only in the presence of one or more activating substituents such as amino or hydroxyl groups. Attack invariably proceeds at a vacant 5-position. Pyrimidines with a single activating substituent are subject only to halogenation; 2-and 4-aminopyrimidines all give 5-bromo derivatives.

Pyrimidines bearing two activating substituents (e.g., pyrimidine-4,6-dione) readily undergo electrophilic substitution at the 5-position giving a series of compounds with the general formula (**1**).

1

E = NO, NO_2, Ph –N=N, halogen

Nucleophilic attack occurs readily at positions 2, 4, and 6. In general, the 4-position is the most reactive. For example, the reaction of phenyl magnesium bromide or phenyl lithium with pyrimidine leads to 6-phenyl-1,6-dihydropyrimidine, which on oxidation gives 4-phenylpyrimidine.

M = Li, MgBr

The reactivity of pyrimidine and its derivatives has been comprehensively reviewed [4].

3. Production

The most general types of ring closure applicable to the preparation of pyrimidines are illustrated below. Other approaches are possible but are rarely utilized.

Type A syntheses are usually the most successful, and over 80 % of all known pyrimidines have been prepared in this way. A typical example is the condensation of urea with diethyl malonate to give barbituric acid. For information regarding other barbiturates see →Antiepileptics, Chap. 2.1.; →Hypnotics, Chap. 5.1.

The synthetic utility of this reaction is greatly enhanced by the fact that any compound containing the group $H_2N{-}C{-}NH_2$ can take the place of urea. Thus, guanidines are precursors to 2-aminopyrimidines, amidines give 2-alkyl or aryl-substituted pyrimidines, and thioureas lead to pyrimidine-2-thiones. The ester group in diethyl malonate can also be replaced by other groups (e.g., keto, aldehyde, nitrile, acid chloride and imino moieties) opening the way to a wide variety of pyrimidine derivatives.

The most common example of a type B synthesis is the reaction of an isocyanate with a 3-aminoacrylate derivative to yield a uracil.

2-Alkyl pyrimidines are readily accessible by type C syntheses. Condensation of 1,3-diaminopropane with the appropriate carboxylic acid, followed by cyclization, results in the dihydropyrimidine **2**, which on dehydrogenation with palladium/alumina affords the 2-substituted pyrimidine **3** [6].

In a similar sequence diamines with a higher oxidation level lead to pyrimidines directly. Thus, malonodiamide condenses with ethyl formate to give 4,6-dihydroxypyridimines [7], and with diethyl carbonate to give 4,6-diaminopyrimidine-2-ones [8].

The Shaw synthesis is an example of a type D synthesis, and is used to prepare many uracil and thiouracil derivatives [9].

Base-catalyzed trimerization of acetonitrile is an example of a type E synthesis, and constitutes a very efficient way of preparing certain pyrimidines (e.g., 2,6-dimethyl-4-aminopyrimidine from acetonitrile) [10].

Other approaches to pyrimidines have been reviewed elsewhere [4].

4. Important Naturally Occurring Derivatives of Pyrimidine

Ortic acid [*65-86-1*], $C_5H_4N_2O_4$, M_r 156.10, *mp* 345 – 346 °C, is thought to be the key precursor in the biosynthesis of all naturally occurring pyrimidines. It can be synthesized directly from urea and oxalacetic acid ester [11]. It has been used in combination with 4-amino-5-imidazole carboxamide for the treatment of liver disease [12].

Uracil [*66-22-8*], $C_4H_4N_2O_2$, M_r 112.09, *mp* 335 °C, is widely distributed in nature, since it is a constituent of nucleic acids. Synthesis: reaction of malic acid and urea in concentrated sulfuric acid [13]. Uracil is an excellent starting material for the preparation of pyrimidines, pteridines, and purines.

Thymine [*65-71-4*], $C_5H_6N_2O_2$, M_r 126.11, *mp* 335 – 340 °C, unlike uracil, is not found in ribonucleic acid but in deoxyribonucleic acid. Synthesis: treatment of 3-methylmalic acid with fuming sulfuric acid to yield 2-formylpropionic acid, which in turn condenses with urea to give thymine [14].

Alloxan [*50-71-5*], $C_4H_2N_2O_4$, M_r 142.07, *mp* 256 °C (decomp.), turns pink at 230 °C and forms mono- and tetrahydrates which lose water at 150 °C. Alloxan induces permanent diabetes in many animals, but not in humans. The best synthetic route to alloxan is direct oxidation of barbituric acid with chromium trioxide [15].

Cytosine [*71-30-7*], $C_4H_5N_3O$, M_r 111.10, *mp* 320 – 325 °C (decomp.), is widely distributed in nature. Since it is a constituent of nucleic acids it can be isolated by hydrolyzing thymus nucleic acids. The principal synthesis is from 3,3-dihydroxypropionitrile and urea [16].

Thiamine [*59-43-8*], vitamin B_1 (→Vitamins), is a very important pyrimidine, manufactured at a level of about 2000 t/a. Synthetic thiamine is prepared in a multistage process. The starting material is acetamidine, which is condensed with the formyl derivative of ethyl 2-ethoxypropionate to give 5-ethoxymethyl-4-hydroxy-2-methylpyrimidine. The heterocyclic thiazole component is introduced in the form of 5-(2′-hydroxy)-4-methylthiazole [17].

Numerous bicyclic heterocycles contain the pyrimidine nucleus, including the purines adenine and guanine, which are important basic constituents of nucleic acids (→Nucleic Acids, →Purine Derivatives).

5. Industrially Important Pyrimidines [18, 19]

5.1. Pharmaceuticals

Pyrimidine derivatives constitute a major class of important pharmaceuticals and have been comprehensively covered elsewhere:

→Antibiotics (e.g., polyoxines); →Antidiabetic Drugs (e.g., sulfonamido pyrimidines); →Antihypertensives, Chap. 5.2.3. (e.g., minoxidil); →Cancer Chemotherapy, Chap. 2.2. (e.g., fluoropyrimidines); →Chemotherapeutics, Chap. 2.7.3.7. (e.g., sulfamethoxazole, trimethoprim, sulfisoxazole, sulfadiazine, sulfacytine), →Chemotherapeutics, Chap. 2.7.3.8. (e.g., sulfadoxine), →Chemotherapeutics (e.g., pyrimethamine), →Chemotherapeutics, Chap. 4.6.1. (e.g., pyrimidine nucleosides and nucleotides). The articles →Anesthetics, General, Chap. 3.1., →Antiepileptics, Chap. 2.1., and →Hypnotics, Chap. 5.1., all deal with barbiturates. Important pyrimidines that do not fall within these categories are summarized below.

Thonzylamine hydrochloride [*63-56-9*], $C_{16}H_{23}ClN_4O$, M_r 322.83, *mp* 173 – 176 °C, is used as an antihistaminic drug. It is prepared by treating the sodium salt of 2-(4-methoxybenzyl)aminopyrimidine with *N,N*-dimethyl-2-chloroethylamine [20].

Piribedil [*3605-01-4*], $C_{16}H_{18}N_4O_2$, M_r 298.35, *mp* 98 °C, is a central dopaminergic agonist used as a peripheral vasodilator. It is prepared by treating 1-(3′,4′-methylenedioxybenzyl) piperazine with 2-chloropyrimidine in the presence of a base [21].

Citicoline [*987-78-0*], $C_{14}H_{26}N_4O_{11}P_2$, M_r 488.33, is a coenzyme in one of the biosynthetic pathways leading to lecithin. It can be isolated from liver and yeast. Citicoline is of clinical use as a central circulation stimulant. It is produced industrially by biochemical action of *Brevibacterium ammoniagenes* on cytidine 5′-monophosphate and choline [22].

Cytarabin [*69-74-9*], $C_9H_{13}N_3O_5$, M_r 243.22, *mp* 212 – 215 °C, is used for the treatment of leukemia and is also active against herpes. Cytarabin is synthesized by treatment of 2,4-dimethoxypyrimidine with 2,3,5-tri-2-benzyl-D-arabinofuranosyl chloride to give the 4-methoxypyrimidone (**4**: R = CH_2Ph, X = OCH_3Me), which undergoes aminolysis with ammonia to the corresponding amine (**4**: R = CH_2Ph, X = NH_2). Subsequent hydrogenolysis leads to cytarabin (**4**: R = H, X = NH_2) [23].

4

5.2. Agrochemicals

Certain pyrimidines are also important agrochemicals: →Fungicides, Chap. 8.7. (e.g., ethirimol and bupirimate); →Insect Control, Chap. 6.6. (e.g., diazinon, pirimiphos), →Insect Control, Chap. 7.1. (e.g., pirimicarb); →Nematocides, Chap. 4.3. (e.g., diazinon).

Pyrimidines are also being used in the newer generation of agrochemicals. Examples follow.

Bensulfuron-methyl [*83055-99-6*], $C_{16}H_{18}N_4O_7S$, M_r 410.4, *mp* 185 – 188 °C, is an example of a sulfonyl urea, a new class of selective systemic herbicides that inhibit biosynthesis of the essential amino acids valine and isoleucine, thereby interrupting cell division and plant growth. Bensulfuron-methyl is used

in the control of annual and perennial weeds in rice [24].

Nuarimol [*63284-71-9*], $C_{17}H_{12}ClFN_2O$, M_r 314.7, *mp* 126 – 127 °C, is a systemic fungicide that acts by inhibiting ergosterol biosynthesis. It is used to control a wide range of pathogenic fungi, such as powdery mildews on fruit [25].

5.3. Dyes

Pyrimidines are also used in the dye industry [26]. The most important examples are the isoindoline pigments, *Pigment yellow 139* [*36888-99-0*], $C_{16}H_9N_5O_6$, M_r 367.27, is used for the coloration of paints and plastics. It is synthesized from 1,3-diiminoisoindoline and barbituric acid [27].

Pyrimidines of lesser industrial importance are discussed in [18, 19, 26].

1. Introduction

The word "pyrotechnics" is derived from a Greek term *pyros techneion* roughly meaning "the art of working with fire." A comprehensive definition was devised in the 1970s by a German working group [1]: "Pyrotechnics is the science of the manufacture and use of articles containing single substances or mixtures of substances whose exothermic chemical reaction is designed to produce desired acoustic, incendiary, thermal, illuminative or luminous, fog, smoke, irritant, pesticidal, propulsive, and/or igniting effects." Ellern has defined pyrotechnics as the art and science of creating and utilizing the heat effects and products from exothermally reacting, predominantly solid mixtures or compounds when the reaction is, with some exceptions, nonexplosive and relatively slow, self-sustaining, and self-contained [2].

The use of mixtures of energy-rich chemicals for the production of heat, light, smoke, or sound is a tradition extending over millennia. Sources assert that the first applications of pyrotechnic mixtures were associated with natural deposits of saltpeter (niter) in China and India [3]. Mixtures of saltpeter and sulfur with wood tar or natural asphalt were probably constituents of the first military pyrotechnics, including the "Greek fire" mentioned in the 7th century. Powder recipes reminiscent of types of black powder still in use today were described in Greece during the 8th century and in China around A.D. 1000–1200 [4]. Fireworks designed for entertainment purposes first appeared in Europe and Japan at the beginning of the Middle Ages, long after the destructive and propulsive power of black powder (→ Explosives, Chap. 1.) had already been invoked for numerous explosive applications in mining and quarrying, and in propellant charges for cannons, muskets, and rockets. Fireworks as a source of amusement also had their origin in China. Historical sketches of the introduction, manufacture, and use of fireworks in Europe (especially in Italy, Germany, England, and France), are provided in [5–7].

Numerous national and international pyrotechnic industry associations, trade associations (Hong Kong), and scientific societies are dedicated to promoting the national and international transfer of technical and scientific pyrotechnic information. The principal forum for this exchange are regular international meetings, seminars, and special publications (e.g., the journal *Propellants, Explosives, and Pyrotechnics*). Worthy of particular mention are the international seminars of the International Pyrotechnics Society, IPS (USA); the American Defense Preparedness Association, ADPA; the Fraunhofer Institut für Chemische Technologie, ICT (Germany); the Groupe de Travail de Pyrotechnic Spatiale, GTPS (France); the Royal Armament Research and Development Establishment, RARDE (UK); the Royal Swedish Academy of

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_437

Sciences, Section for Detonation and Combustion (Sweden); and the China Ordnance Society (Peoples' Republic of China). Colloquia dealing with pyrotechnic topics are sponsored by national institutes and societies, e.g., the German Society for Defense Technology (DWT) and the Franklin Research Center (Maryland, USA). Conference proceedings issued by these societies, along with the patent literature, remain among the most vital and current sources of information. Surveys of the entire subject of pyrotechnics, including both civilian and military – industrial applications, are given in [2, 3, 6, 8, 9].

2. Pyrotechnic Compositions

The energy sources for pyrotechnic charges, pyrotechnic munitions, and fireworks are reactive chemical mixtures known as *pyrotechnic compositions*, whose principal components are oxidizing agents, reducing agents, and binders. Formulation aids as anticaking or friction-reducing substances (lubricants) are also included, and in some cases, catalysts.

Oxidizing agents: nitrates [KNO_3, $NaNO_3$, $Ba(NO_3)_2$, $Sr(NO_3)_2$, $NH{=}C(NH_2)_2 \cdot HNO_3$]; perchlorates ($KClO_4$, NH_4ClO_4); chlorates [$KClO_3$, $Ba(ClO_3)_2 \cdot H_2O$]; chromates [$BaCrO_4$, $K_2Cr_2O_7$, $(NH_4)_2Cr_2O_7$, $PbCrO_4$]; peroxides and oxides (BaO_2, SrO_2, PbO_2, Pb_3O_4, MnO_2, ZnO, Fe_2O_3, Cu_2O, CuO); halogen-containing substances [C_2Cl_6, C_6Cl_6, $(C_{2n}F_{4n})_x$].

Reducing agents : metals (Al, Al/Mg, Ca/Si, Cr, Fe, Mg, Sb, W, Zn, Zr/Ni); nonmetals [B, C (graphite, charcoal, activated carbon), P, S, Si]; carbohydrates (sucrose, lactose); inorganic compounds (NaN_3, Sb_2S_3, ZrH_x); organic compounds (sodium salicylate, potassium benzoate, sorbitol, metaldehyde, hexamethylenetetramine, oxalates, tetrazoles, azodicarbonamide, dicyandiamide).

Binders : natural resins (gum acaroid, gum arabic, gum tragacanth, shellac); synthetic resins [polyethylene, poly-(vinyl chloride), chlorinated rubber, polyester, polyurethane]; plasticizers; dextrin; starch; inorganic binders ($CaSO_4 \cdot H_2O$, sodium silicate, bentonite).

Formulation aids : anticaking agents (pyrogenic SiO_2, pyrogenic Al_2O_3, $CaCO_3$, $MgCO_3$); lubricants (graphite, talc, wax, polytetrafluoroethylene).

Catalysts : Fe_2O_3, $CuO \cdot CrO_2$, V_2O_5, MnO_2.

Pyrotechnic compositions usually contain three to six components. Grain sizes vary from 40 – 400 µm for the components, and from 250 µm to ca. 5 mm for the pyrotechnic compositions themselves. The compositions are utilized in loose form (flash compositions) or compressed into granules or pellets to improve meterability. Most pyrotechnic compositions are then pressed into tubes made of cardboard, plastic, or metal. Special shapes are often conferred on the surfaces of both pressed and granulated compositions to ensure specific burn characteristics. With pressed compositions, the degree of compaction depends largely on the level of stress the charge is expected to experience. A satisfactory density is normally attained at 300 bar, but pressures up to 1200 bar are required for severe application stresses (e.g., in tracer charges, which must survive firing).

Ignition introduces a series of complex solid-state redox reactions in which the activation energies of surface reactions play a crucial role [7]. The main energetic product from the pyrochemical reaction of a pyrotechnic composition is electromagnetic radiation in the infrared region ($\lambda = 1 - 5$ µm). The resulting high temperature may be desirable and even useful (as in priming compositions, rocket-propellant compositions, illuminating and signal-flare compositions), but in certain cases the temperature must be controlled to ensure that other components are only vaporized and not degraded (e.g., colored smoke compositions). Stars for display fireworks need not burn at very high temperatures. The deepness and effect of colors are better achieved with temperatures of only 800 – 1000 °C. In an optimized flare composition, little more than 10 % of the radiation output constitutes visible light useful for illumination and signaling purposes; the ultraviolet contribution is only < 0.1 % of total emission. The most effective *illuminating compositions* are mixtures in which magnesium and $NaNO_3$ are combined with polyester or fluorocarbon binders (55 % magnesium, 40 % sodium nitrate, 5 % binder). Along with the oxidation of magnesium by $NaNO_3$ (reaction temperature > 3000 °C), stoichiometric excesses of magnesium (*bp* 1107 °C) and sodium (*bp* 892 °C) undergo combustion in the vapor state with at-

mospheric oxygen, resulting in a large amount of additional energy. The radiation produced in such flares is distributed mainly by MgO and sodium vapor.

Screening smoke compositions are used particularly by the military for concealment and deception. Classic smoke compositions include the hexachloroethane/Zn/ZnO/Al (HC) system, systems based on red phosphorus (RP) and its derivatives, and related formulations that all release or vaporize hygroscopic substances through pyrochemical reactions. The hygroscopic material interacts with atmospheric humidity to form droplet aerosols that are impenetrable to visible light. More recently developed systems utilize pyrotechnic compositions producing solid particle aerosols based on some form of carbon (carbon black, graphite), which extend the concealing effect into the infrared and far infrared (wavelengths in the 3 – 5 and 8 – 14 μm range).

Smoke compositions likewise serve to produce aerosols. For example, the heat of reaction generated in a bed of $KClO_3$ and lactose hydrate can be used to drive off such sublimable substances as dyes (anthraquinones), NH_4Cl, tear gases (CN, CS), or insecticides (lindane).

Gas compositions are widely used in gas generators, propellant charges, rocket motors, and actuators. (→ Propellants, Chap. 5.3.). These compositions are designed to produce a predetermined large volume of gas over a short period of time. Pyrotechnic gas compositions based on NaN_3 and KNO_3 together with appropriate slag formers have found unique application in automobile air bags (active restraint systems).

Delay compositions molded into small diameter tubes are used for the transmission of detonating impulses. They delay the onset of a device's main function by a precisely adjustable time interval which is equivalent to the burning time of the composition. Most compositions of this type contain substances such as metal powders and oxides, or chromates that react without the production of gas, although delay charges for fireworks and simple pyrotechnic munitions may also be made from compressed black powder.

3. Pyrotechnic Effects

Pyrotechnic effects achievable through the high chemical energies of pyrotechnic compositions can all be attributed to a few basic phenomena. A pyrochemical reaction is initiated when the composition is ignited. What follows is an extremely complicated, multicomponent, solid-state process governed by parameters subject to wide variation. The most important factors are the masses and physical states (allotropic form, density, grain size, internal and external surface area, and purity) of the reactive components. In addition, key macroscopic physical parameters include temperature, extent of compaction of the composition, degree to which the components are mixed, and external configuration of the charge (enclosed or bare, burning on all sides or only on one end, or provided with a specially-shaped burning surface). All these factors are exploited for particular effects, and are used to varying degrees depending upon the intended purpose of a given pyrotechnic device, firework, or pyrotechnic munition.

Hot Slags with High Heat Capacity. Compositions that burn with little gas evolution, such as delay and thermal compositions, but also IR-emitters, produce hot slags with a high heat capacity. Particles and slags with prolonged glow times are used in firework compositions to obtain special comet or fountain effects. Slags formed in the heating-bed components of smoke compositions may also serve to vaporize agents that are to be dispersed. Black powder or boron/potassium nitrate pellets may be used as igniter or booster charges with cannon or solid rocket propellants. Their formation of hot spots (slag droplets) improves and increases the effect of the instantaneous ignition of the propellants.

Light Emission. The oxidation of such light metals as magnesium or aluminum, but also titanium and zirconium, is used to produce light. Oxides that result from the combustion reaction (e.g., MgO, Al_2O_3, TiO_2, or ZrO_2) are the sources responsible for the radiation. Silver, waterfall, and fountain effects in display fireworks are achieved in this way, as is the light emission from flash and illuminating compositions. The color of the resulting light

can be influenced by the choice of the oxidizing agent: $Ba(NO_3)_2$ or $Ba(ClO_3)_2 \cdot H_2O$ for green, $Sr(NO_3)_2$ or $KClO_3/KNO_3$ together with $Sr(COO)_2 \cdot H_2O$ for red, $NaNO_3$ or $Na_2(COO)_2$ for yellow, and copper salts for blue. Star and Bengal-illumination firework compositions seldom contain powdered metals; instead, the reducing agents are often natural resins, such as gum acaroid (red gum) or shellac. The resulting light is an order of magnitude less intense, but the colors are stronger and more impressive.

Gas Emission. Compositions that react rapidly, such as loose black powder, are useful for propulsion, ejection, and explosion (as in firecrackers). On the other hand, compositions that burn evenly over well-defined surfaces are important in rockets and gas generators. Colored illuminating compositions that burn with the evolution of large amounts of gas confer an additional illuminating effect on firework rocket exhaust. Such compositions are often included in wheels, suns, ground spinners, and fountains, where they lead to copious emissions. The thermal compositions in smoke-forming and screening smoke charges disperse clouds of vapor that condense in the air. The smoke-forming charges rely on colored aerosols of sublimable, oxidation-resistant dyes, whereas highly hygroscopic $ZnCl_2$ or P_2O_5 from the latter combine with atmospheric water vapor to form dense masses of fog (screening smoke).

Oscillating Combustion. Whistling and continuously flashing compositions take advantage of intermittent burning. With whistling charges, competing reactions withdraw so much energy from their immediate surroundings that they nearly quench the main reaction (e.g., $KClO_4$/potassium benzoate). In flashing charges, the main reaction is interrupted by one or more "dark reactions" in which one of the principal components is first converted to a pyrophoric, partially oxidized slag [10]. This slag then undergoes further reaction, generating a burst of light, after which the original dark reaction resumes its normal course (e.g., Mg/Al-alloys in $Ba(NO_3)_2$- and $Sr(NO_3)_2$-based compositions).

4. Fireworks

Fireworks have always been popular because of their capacity to bring pleasure and beauty, permitting gunpowder (black powder) to make some amends for its evil reputation as a source of death and destruction. Fireworks have been fabricated since the earliest of times, but prior to the nineteenth century and the advent of modern chemistry they must have been relatively dull and unexciting. During this time the golden color produced by a combination of gunpowder and charcoal with various fats, waxes, oils, and natural resins stimulated the production of rockets, cannon shots, and various types of flames. Our forebears also made some use of iron and antimony, but they would have been stunned by the range of effects available today.

The discovery by BERTHOLLET in 1786 of the oxidizing potential of $KClO_3$ led to a new era in fireworks some forty years later through the introduction of colors (e.g., red, blue, and green). $KClO_3$ alone with fuels produces a weak purple color. It is the salts of copper, barium, strontium, or sodium that provide the intense color, since $KClO_3$, for example, converts the strontium salt to SrCl in the flame. However, $KClO_3$ was also a source of many problems in later years because of its inherent instability in pyrotechnic mixtures and the undesired simultaneous presence in early preparations of highly unstable $Ca(ClO_3)_2$. Whenever possible, $KClO_4$ is now utilized instead.

The next great leap forward came with the development of electrochemistry and subsequent isolation of the metals aluminum and magnesium. Aluminum was a great gift to firework makers, in that it added a brilliant silver dimension to the available effects. Magnesium was equally important, but since corrosion does not lead to a protective oxide layer, unlike aluminum, corrosion continues unabated.

In recent times nothing has been added that was desperately new and eye-catching. Titanium's availability as a noncorrosive metal brought only another silver effect, and while it offers certain commercial advantages, these are offset by the fact that titanium's hardness raises friction problems; sparks created by hard metal particles rubbing against each other can ignite the whole mass.

Advances in chemical technology have also provided a variety of interesting complex compounds, many of which have contributed to a gradually maturing understanding of pyrotechnic reactions. For example, such halogen-donor additives as poly(vinyl chloride), chlorinated rubbers, and chlorinated hydrocarbons have been used to improve color; metal halides are then responsible for the flame color by producing unstable molecules such as SrCl, BaCl, or CuCl. The introduction of polymerizing resins was another important development. Experiments with these resins attempted to solidify pyrotechnic compositions into a hard mass. The solids were mixed with liquid resins and then cast into molds; this avoided the traditional use of hydraulic pressure. SOBRERO's discovery of the explosive properties of nitroglycerine and its extensive commercialization by NOBEL inevitably signed the death warrant for large-scale use of black powder, although it remains an essential ingredient in fireworks, both as an explosive and as a propellant. Europe and North America began importing large quantities of Chinese fireworks during the 1960s. Many assume that fireworks actually originated in the East, but this is not the case. Although the Chinese may be credited for pioneer work with black powder and firecrackers, modern fireworks are very much a western development, and western technology has been transported back to the East only during the twentieth century. Interestingly, since World War II the Chinese have pursued their own independent course, with the result that native compositions, ingenuity, and cheap labor have given rise to a new approach. For many years the West has thus had access to ingenious, intricate, little fireworks based on bright magnalium flames that would have been very expensive to produce domestically.

4.1. Shop Fireworks

Shop fireworks are sold directly to the public throughout the world, usually in conjunction with some holiday or special event: New Year's Eve, a national day like July 4th (Independence Day in the United States), or a special occasion like November 5th in England. Age restrictions are increasingly being applied to the sale of shop fireworks (e.g., 16 in the United Kingdom and 18 in Germany), as are limits on the types of fireworks available for purchase, their size (caliber), and their net explosive content (Chap. 7).

Shop fireworks are also usually subject to a restricted sales period, but this varies widely. For example, the authorized period of sale before New Year's Day in Germany is only two and a half days, but it is three weeks in the United Kingdom prior to the November 5th celebration. Shop fireworks consist mainly of *toy fireworks* and *garden fireworks* (Class 1 and 2 fireworks in Germany, France, and other European countries; see Chap. 7).

4.1.1. Toy Fireworks

Toy fireworks are generally indoor or hand-held devices, such as sparklers.

Amorces and Pistol Caps. Although these items are widely distributed, they are made with the dangerous combination of $KClO_3$ and amorphous red phosphorus. The mixture has to be handled as a wet slurry, and is explosive at low concentrations of water. As the mixture is extremely sensitive to impact and friction only a tiny spot is placed between two layers of paper or into a tiny cup and then dried. It is also used in plastic rings for repetitive fire in toy pistols.

Sparklers. These popular fireworks, known as "Wunderkerzen" in Germany, release a prolonged shower of relatively harmless sparks upon ignition. They are made by dipping wires into a slurry of $Ba(NO_3)_2$, powdered aluminum, and powdered iron. The best sparklers are fabricated by a process similar to matchmaking (→ Matches, Chap. 3.), employing essentially the same adhesives and high temperatures, but this approach is too expensive for the manufacture of cheap commercial products. Good sparklers must not drop hot slag, and the wires must not bend during use.

Snakes. This German discovery ("Schlangen") is unique and unpleasant to prepare as it involves the use of fuming nitric acid and produces large quantities of NO_2 gas. The choice of pitch, and the strength of the acid which nitrates it are important considerations. The snake is formed when the nitrated pitch

has burnt and the liquid ash of the reaction is blown up by gaseous decomposition products. The results are extraordinary – a 15 mm pellet produces a snake more than a meter long.

Table bombs utilize nitrocellulose made from cotton wool to eject their contents. They usually consist of a paper tube with a fuse at the base which connects directly with the nitrocellulose charge. A disk on top of the charge has the dual purpose of lifting the toys or other items and preventing them from being scorched. *Indoor fountains* are also made with powdered nitrated cellulose.

Throwdown crackers ("Knallerbsen" in Germany) are made from silver fulminate (AgOCN). A grain of this material is placed in a twist of paper with sharp sand; a sharp crack is produced when it is thrown onto the ground. Packing for transportation needs careful control.

4.1.2. Garden Fireworks

Garden fireworks are regarded as Class 2 fireworks in Europe. Most are smaller versions of large display fireworks, and the restrictions to which they are subject vary widely. Rockets for sale in shops are identical to display rockets (Fig. 1) except for being smaller. The powder content of Class 2 rockets is limited (e.g., 20 g in Germany). The general public in France, Switzerland, and the United Kingdom is still permitted to purchase relatively large rockets and even star shells.

Bengal illuminations are an important feature of many firework displays, particularly effective for illuminating parks and buildings. They can be produced in any color, but traditionally they are red or green. They are invariably made from $Ba(NO_3)_2$ or $Sr(NO_3)_2$ with added $KClO_3$ and a suitable fuel such as acaroid resin. As they burn slowly, a large quantity of ash is produced. It is therefore necessary to burn them horizontally. The reflected light produced by these devices is much more attractive than the direct view into a flame, so they are frequently placed behind a barrier.

Figure 1. Rocket
a) Stabilizing stick; b) Fuse protection; c) Fuse; d) First fire; e) Nozzle; f) Propellant; g) Delay; h) Expelling charge; i) Rocket tube; j) Stars; k) Sealing material; l) Cap

Firecrackers. Popular with young people as a way of producing a loud noise, firecrackers (or "bangers") have been a source of considerable criticism of the firework industry. In former times they were prepared from $KClO_4$ and aluminum, but most now utilize black powder in an attempt to restrict the resulting noise and flash levels. Every country sets its own limits on the permissible size and black powder content of firecrackers. In the United Kingdom the limit is as little as 1.6 g, whereas in Germany it is 10 g. The burning time of the fuse is a critical parameter in all firecrackers. It must obviously not be too short, but it should also not be too long, because the user may wrongly conclude that the device has failed. A delay of 3 – 6 s is generally regarded as optimal. Methods of igniting firecrackers vary from country to country. In Germany they are often ignited with either a matchtype friction igniter or a black powder fuse, while the United Kingdom displays a pref-

erence for blue igniter paper soaked in KNO_3 (blue touch paper).

Fountains play a central role in garden fireworks, in part because they exist in so many different forms. For children, they may take the form of *golden* or *silver rains*. These are composed of black powder and charcoal, with aluminum or titanium added for a silver effect and iron added for a golden effect. Brilliant *silver jets* utilize $Ba(NO_3)_2$ and aluminum, or black powder and titanium; these are highly prized in France, where they are called "vif argent". Some fountains generate a colored fire made more dramatic by the presence of magnesium–aluminum (magnalium) alloy, which results in large silver crackles and flickering ("strobe") effects. Fountains were formerly made in the United Kingdom from a black-powder mixture containing lampblack and As_2S_3, which formed beautiful and distinctive golden corruscations. However, since lampblack is too dirty to handle and As_2S_3 unobtainable and toxic, these components are now no longer used. Iron powder that has been suitably coated with linseed oil or acaroid resin to prevent corrosion also leads to golden effects. Most garden fountains produce relatively gentle performances, unlike the fierce jets featured in displays.

Display fountains have internal diameters ranging from 18 to 30 mm. They contain large quantities of black powder to produce columns of fire whose height may exceed 2 m. Beautiful patterns may result when several such fountains are carefully fastened to wooden posts and then ignited simultaneously. Similar or slightly modified jets can also be used to turn wheel pieces. In some parts of the world, fountains are prepared with diameters as large as 75 mm, producing high, roaring jets that resemble geysers.

Volcanoes are fountains with cone-shaped tubes that gradually increase the height of the fire and its output of sparkles.

Whistles (Fig. 2) never cease to fascinate people, and when carefully constructed they can provide a wide variety of sounds. It was once thought that the sound emitted had an essentially mechanical origin, but it is now recognized that it results from gas evolved at the base of an empty tube that acts like the resonator of an organ pipe. This gas is generated in an oscillating fashion, with a frequency of ca. 3000–4000 Hz. Differences in tone result from modifications in the diameter and length of the tube, from appropriate design of the surface of the pressed pyrotechnic composition, or the fact that the resulting gas is forced through a nozzle. Special effects are also achieved by burning a whistle at both ends of the tube, but with different lengths of open tubing.

Figure 2. Whistle
a) Fuse (quickmatch); b) Paper or plastic foil; c) Paper tube; d) Whistle composition; e) Clay seal

The chemicals utilized as fuels in whistling systems are aromatic carboxylic acids (e.g., 3,4,5-trihydroxybenzoic acid, benzoic acid salts, salts of salicylic acid, phthalic acid, terephthalic acid and derivatives). The earliest whistling compositions contained potassium and sodium picrate, but these proved to be very dangerous. One of the first whistling mixtures prepared on an industrial scale was made from $KClO_3$ and gallic acid (3,4,5-trihydroxybenzoic acid). Extremely sensitive to impact and friction, this mixture has been the source of many accidents, and is no longer used. Most mixtures today are composed of $KClO_4$ and potassium benzoate, sodium benzoate, sodium salicylate, or a mixture of these fuels. Chinese firework manufacturers now employ monopotassium terephthal-

ate. Each whistling formulation must be manipulated in a different way. All whistling compositions are hazardous and must be handled with great care.

4.2. Display Fireworks

Rockets are display fireworks which have their own means of propulsion in the form of a gas stream; their flight is invariably stabilized with sticks, fins, or other more sophisticated devices. *Shells* are actually bombs launched from mortar tubes. A third type of display firework is known as a *mortar mine*. The firework effect discharges from a mortar tube at a height of 3 m to 20 m. A column of stars, crackers, and noisemakers is ejected from ground level to this height. The calibers vary from 40 mm to 100 mm. All three fireworks produce very similar aerial effects.

Rockets (Fig. 1). The first firework rockets utilized as their propellants modified gunpowder mixtures (typically 61 % KNO_3, 5 % sulfur, and 34 % charcoal), but the proportions of the ingredients can vary considerably. The burning rate of the powder must be controlled to ensure consistency, and this requires some technical skill. Thus, the manufacturer must carefully regulate the amount of gas issuing from the rocket venturi (nozzle) by adjusting the burning surface area of the composition. Firework rocket motors traditionally consisted of a paper tube partially closed at one end by a clay washer. The hole in the washer may be as much as half the diameter of the washer itself. The center of the rocket tube is occupied by a spindle-shaped space offering sufficient burning area to produce a large quantity of gas. In practice, the composition is pressed around a metal spindle, which is subsequently withdrawn. The process is completed by pressing a diameter of powder onto the top of the spindle to create a delay sufficient to permit the rocket to reach its maximum height before stars are ejected.

Firework rockets are fitted with a very lightweight cap filled with colored stars or noise units, which are ejected by the detonation of small bursting charges. Locating the rocket's center of gravity immediately below the venturi ensures that the device will rise vertically, particularly if the stick is a bit heavy. During its upward climb a rocket tends to turn toward the wind because the stick is forced into a downwind position.

Traditional methods of rocket production are subject to many technical problems because of the large burning surface area and the fact that a three component mixture can vary in its burning speed. Modern rockets are formulated with black powder containing a small amount of graphite as this increases the control of the burning speed and aids the pressing operation. The nozzle has become smaller in diameter due to the increased burning time resulting in a smaller burning surface area, and only a slight indentation is made into the powder to increase the initial thrust. Rockets of this type are not as attractive as traditional ones, since both the golden trail and the maximum height are reduced, but they are easier and cheaper to produce, and they are also more reliable. The replacement of paper tubes by aluminum or hard cardboard also facilitates the use of molds for large-scale pressing of the charge.

Rockets are a special feature of Spanish firework displays, which often achieve the most magnificent effects from hundreds of 14-mm rockets fired in a single volley. The Portuguese also utilize enormous rockets (with sticks longer than 2 m) featuring multiple effects.

Roman Candles (Fig. 3). The Roman candle is thought to have been English in origin, and this name is used worldwide. Essentially it is a long, narrow tube, and is a stationary device. Stars, noise units, or little bombs are ejected at short intervals by positioning some kind of delay mechanism between each item. A small charge of blackpowder is placed in the bottom of the closed tube, followed by the projectile star and then a small amount of blackpowder to ease the ejection. The delay is placed on top of the blackpowder. In cheap items it is usually a modified black powder mixture containing black powder mixed with KNO_3, sulfur, and charcoal, which burns slowly. This arrangement is repeated to produce one to ten shots over a period of 20 or 30 s. Well-made items eject 16 – 18 mm stars regularly to the same height, but cheaply-produced oriental items can produce as many as 30 shots with poor consistency.

Figure 3. Section of a 30 mm candle
a) Plug; b) Star; c) Felt wad; d) Grain gunpowder; e) Delay

Commercial Roman candles would normally have a caliber between 10 and 20 mm; however, military thinking has considerably advanced the Roman candle technique during the 1970s and 1980s, with the result that excellent items are made in much larger bores from 28 up to 60 mm. In such large diameters black powder-type delay compositions are unreliable and produce too much flame and smoke, to say nothing of the high cost and elevated net explosive content. This problem has been overcome by replacing the bulky powder delay with a pure wool-felt wad that is forced tightly into place. A much smaller delay mechanism in the center of the felt is responsible for transferring the fire. Some manufacturers have devised plastic inserts, and although these are reliable substitutes, they lack the flexibility of felt.

Bombs and Shells. It may be argued that shells are the most spectacular of all fireworks, and that they offer the greatest variety. In the earliest times military personnel managed most civilian firework displays, and bombs and shells for both military and civilian use therefore developed in tandem. The principle underlying these devices is propulsion of a round or cylindrical projectile from a mortar or gun. For civilian applications projectiles had to be made of paper, although paper has been replaced at least in part by plastic.

It was once assumed that bombs should be spherical (Fig. 4), and for many years they consisted of strong paper hemispheres glued together with extra paper pasted on the outside. Firework stars and gunpowder filled the inside, and the sphere was fitted with a time fuse to ensure ignition at maximum height. The contents were invariably dispersed in a disorderly way into the air, with the two paper hemispheres falling to the ground. Some of the fragments could be quite large, since displays often included balls 250 or 300 mm in diameter. Charges of black powder were used to project the bombs.

Figure 4. Spherical shell (bomb)
a) Propellant charge (black powder); b) Casing; c) Delay; d) Bursting charge; e) Effect units (stars, etc.); f) Shell case; g) Quickmatch

A sphere is clearly not the optimum ballistic shape, and inevitably there was a move from spherical bombs toward cylindrical shells

(Fig. 5). Originally pioneered by the Italians, many large, beautiful, cylindrical shells are still produced today. The shell body is not particularly strong; it consists primarily of several layers of paper rolled around a cylindrical former. The interior is very carefully but completely filled with gunpowder and stars, noise units, or other effect items to form a solid projectile. The ends are then closed and the device is fitted with a time fuse. Binding the cylinder with many horizontal and vertical turns of string provides additional density and integrity, creating a durable projectile more resistant to the shock of the propelling charge. For further protection during the firing stage, the cylinder's thin paper walls are covered with additional paper. The debris from modern cylindrical shells is less dangerous than that from the earlier spheres, because it consists mostly of bits of paper and string.

Figure 5. Cylindrical shell
a) Propellant charge casing; b) Propellant charge (black powder); c) Delay; d) Effect-carrying subunits; e) Bursting charge; f) Tube; g) Quickmatch

Several shells can be placed inside one another as a way of producing several pyrotechnic sequences from a single firing. Cylindrical shells may be as large as 25 cm in diameter and 75 cm long, but also as small as 50 mm in diameter. Because of the handwork involved, good Italian shells are expensive, yet a joy to view, especially the large specimens fired individually at the beginning of a display as encouragement for the audience to savor the skill of the pyrotechnist.

The next stage in shell development originated in Japan. Japanese fireworks utilized only black powder until 1880, when $KClO_3$ was first introduced from Europe. However, the distinctive Japanese "warimomo" (chrysanthemum) shell first appeared in 1926. These elegantly patterned devices are spherical and are surrounded by thick layers of pasted paper to provide perfectly balanced resistance against the strong, bursting charge in the center of the shell. Preparing the pasted outer layer is time-consuming and expensive, and requires considerable skill; achieving a given number of equivalent pasted-paper layers on the outside of a sphere using only paper strips is no easy task!

The Japanese also developed spherical stars, which are made by layering one star color over another to provide two or three changes of color. Great manufacturing skill is required to create the impression that all the stars from a given shell change color simultaneously. Methods have also been devised for creating patterns from such shells, causing letters, star-like shapes, spirals, interlocking circles, and various other novelties to appear. Nonetheless, there are limitations; many of the most dramatic effects require observation in a specific viewing plane, which means that the shell must burst in a particular way to prevent spectator disappointment. Ropes and weights have sometimes been attached to the shells to achieve this. Patterns can be produced with Japanese shells by working with stars of different diameters, since larger, heavier stars tend to be projected farther than the lighter, smaller ones. Beautiful flower effects have been achieved in this way, some featuring central pistils of contrasting colors.

The inevitable rise in the cost of manual labor has caused manufacturers to seek new ways of reducing the expenses involved in shell production. Some look to third-world countries for their supplies, but others fabricate their shell bodies from high-density polyethylene, which simplifies the manufacturing process regardless of whether the device is spherical or cylindrical. On the other hand, debris represents a potential problem with plastic shells, and in some coun-

tries there is talk of prohibiting such materials. Manufacturers are therefore looking forward to the discovery of a suitable biodegradable material.

Countries vary in their attitudes toward the handling of shells. In France and the United Kingdom, for example, the public is permitted to purchase and use shells up to 100 mm in caliber, whereas in Germany such large shells are restricted to professionals. There are also differing opinions regarding the "safe distance" for firing shells in public. The United Kingdom issues only general recommendations, but other countries, (e.g., the United States) are attempting to establish a uniform code (e.g., a surrounding radius of 21 m for each 25 mm of shell diameter, so that a 75-mm shell would require a display site of 63 m, a 100-mm shell would require 84 m, etc.). However, these guidelines are only approximate as so much depends on the nature of the site.

Figure 6. Mortar mine (in mortar)
a) Wooden seal; b) Mortar tube (cardboard); c) Propellant charge (black powder); d) Effect subunits (stars, etc.); e) Paper bag; f) Quickmatch; g) Delay (connecting fuse)

Mines (mortar mines) are used in combination with other fireworks for public displays. A mine is essentially a simplified form of a bomb (Fig. 6). A launching tube is required just as with a bomb, but the mine bursts within the launching tube rather than being first projected into the air. This produces a long column of sparks, colored stars, and noise starting at ground level and extending to a height of 25 m. The effect is very dramatic, because the visual impact is much closer to the spectators than in the case of a bomb or shell. Mines are typically designed for mortar tubes 75 – 125 mm in diameter, but 30 – 40-mm mines are also produced for direct sale to the public.

Combinations. Many of the fireworks described so far lend themselves to combinations, in which a rapid-firing fuse causes the various units to ignite almost simultaneously. Such a fuse is called a "quickmatch," and consists of long strands of cotton that have been passed through a slurry of black powder. When dry, the fuse burns quite steadily in air, but placed inside a narrow paper tube it burns almost instantly as a result of the increased temperature and pressure. *Wheels* are created by tying fast-burning fountains onto pieces of wood pivoted at their centers so they will spin. Fountains can also be attached to stationary wooden structures in conjunction with colored lights and small wheels to produce complex fire patterns.

Water fireworks rely on fountains that have been floated on pieces of cork. Shells are sometimes fired on the water to add dramatic effects, in which case waterproof fuses must be used. Larger shells are often encased in polystyrene foam to help them float.

Fire pictures are created from small, colored lights called lances (each about the size of a cigarette) that burn for almost a minute. Lances are made from $KClO_4$ with the addition of fuel, coloring agents, and intensifiers. When spaced along a piece of wood or cane the tiny pinpoints of light from these small fireworks merge to form an outline, although the projected outlines must be kept quite simple for maximum effectiveness.

The ever-popular *waterfalls* are made from brilliantly-burning aluminum incendiary compositions in combination with barium nitrate or $KClO_4$.

5. Pyrotechnics for Industrial and Military Use

Pyrotechnic devices for industrial and military use include munitions for illumination, communication, and emergency signaling; gas generators; actuators; detonator subassemblies; tracers for many conventional munitions; and smoke

devices. In these applications, chemical energy stored within a pyrotechnic composition is released selectively in order to perform useful work (gas generators, actuators), convey information (signaling and emergency munitions, colored smoke generators), mark the trajectory of a projectile (tracers), transfer a firing impulse (delay fuses, priming charges, intensifying charges), or provide concealment (smoke generators, smoke munitions). Smoke-generating compositions find special application in cartridges designed to release insecticides or irritants, especially in police tear-gas munitions.

A trigger mechanism is used to activate these pyrotechnic devices. Generally, this is a primer cap which is ignited through the percussion of a firing pin (percussion cap) or by friction (friction igniter). Other triggering mechanisms incorporate electrical bridge initiators, striking heads, or black powder priming fuses.

The method used to transmit and intensify the initiating impulse varies. For munitions in cartridge form, a propellant charge is ignited immediately after primary ignition to convey the effective or working part of the pyrotechnic munition to the desired point of application. For munitions designed to perform their function at the site of initiation (signaling and illuminating flares, smoke generators), the initiating impulse is transmitted directly to the pyrotechnic illuminating, signaling, or smoke composition by a booster or transfer charge. In some cases safe use of a devide dictates the incorporation of a pyrotechnic delay column, whereby activation of the effect charge occurs only after the time-delay element has functioned. Delay columns are also utilized when active components (bombettes) within a pyrotechnic munition in cartridge form must be ignited some time after the device has been discharged from the firing weapon (Fig. 7). Use of an auxiliary delay element (or a rocket propellant composition) permits a signal to be displaced a considerable distance from the point of release.

The intended locus of action for such a signal has a significant influence on the design of the device. *Items intended for stationary operation*, such as signal flares, alarm flares (Fig. 8), alarm mines, smoke-signal generators (Fig. 9), floating smoke signals, and illuminating or marking devices for release from aircraft, always have a simple, robust construction. A priming element and an intensifying charge (booster and intermediate compositions) may cause the main charge to be ignited directly, but safety considerations may force ignition to be delayed as described above.

Figure 7. Illuminating cartridge with rocket and parachute a) Percussion cap; b) Propellant charge; c) Cartridge tube; d) Propellant (rocket); e) Delay charge; f) Illuminating star; g) Parachute; h) Sealing disks

Pyrotechnic munitions in cartridge form, with propellant charges, (Fig. 7) often differ significantly from devices for stationary use. Once such a munition has been activated, the component containing the pyrotechnic element is accelerated by combustion gases released from the propellant powder, permitting it to escape from

both the propellant casing and the launching device (e.g., a signal pistol).

Figure 8. Illuminating alarm flare
a) Percussion cap; b) Starter composition; c) Transition charge; d) Illuminating charge; e) Case; f) Sealing cap

Figure 9. Smoke grenade with friction igniter
a) Friction igniter; b) Delay column; c) First fire; d) Transition charge; e) Smoke composition; f) Aluminium case

The *"non-self-propelled single-star munitions*" utilize the igniting impulse from the propellant charge or primer cap (Fig. 10) directly for activation of the pyrotechnic composition. Shortly after the device leaves the muzzle of the launcher, the effect composition (e.g., a red star) is ignited by a transition composition, which may consist of both a booster and a transition charge. The resulting signal is seen as a red light travelling away from the firing point. A *pyrotechnic tracer* (Fig. 11) incorporated into a conventional projectile operates in a similar way. If a pyrotechnic signal is to be activated at some predetermined distance from the firing point (e.g., to provide better or extended visibility, or as a way of avoiding betrayal of the shooter's location), the propellant charge first ignites a delay element or a rocket-propellant composition.

Pyrotechnic signal munitions in cartridge form, and incorporating the design features described (Fig. 7 and 10), are most frequently encountered in Europe in the following metric calibers: 15, 16, 19, 26.5, 28, and 40 mm. Typical sizes in Anglo-Saxon countries, and especially the United States, include 1 in and 1.5 in. The 15-mm devices, especially in Germany, are in- creasingly taking on the character of fireworks, and are mainly produced for this purpose. Larger caliber devices are used by the military and for emergency signaling in both maritime- and mountain-rescue operations.

Two classes of pyrotechnic munitions, training munitions and simulation devices, are reserved almost exclusively for military purposes. Pyrotechnic *training munitions* combine the potential for realistic training with the advantage of low cost. The associated aiming and firing operations are identical to those for live munitions, but the appropriate sound effects (report) and the trajectory in the case of a projectile or rocket are reproduced or simulated pyrotechnically.

Simulation devices are employed in training maneuvers as a way of evoking the sense of a field of battle, for example, or the effects generated by various types of weapons. Pyrotechnic charges are thus used to simulate the firing and impact of grenades (Fig. 12), artillery strike points, the elimination of a target (e.g., a tank), or the use of a weapon requiring specific countermeasures on the part of the troops.

6. Production

Most of the larger pyrotechnic producers are affiliated with the chemical industry. The majority originated as family enterprises, and some remain family operations or combinations of such ventures. These firms have devoted their efforts primarily to the fabrication and presentation of public firework displays, but also to the production and marketing of small fireworks. Larger firms in central and southern Europe, the United States, and Japan have long since adopted industrial-scale production techniques. This applies especially to operations in which fireworks manufacture is linked to industrial and military product lines, where the latter often account for most of the sales. Middle-sized operations with 10 – 300 employees continue to typify the pyrotechnic industry. Most are purely family ventures (especially around the Mediterranean), but some operate as independent divisions of larger corporations, particularly as specialized branches of armaments manufacturers [for example, COMET (Diehl group) and NICO (Rheinmetall group)]. Smaller "fireworks-only" firms produce display fireworks (bombs, fountains, rockets, and garden displays) almost entirely by hand, relying on traditional recipes and techniques (see Chap. 4).

Although a highly specialized and traditional craft, professional training in the field of pyrotechnics is nonexistent in virtually all the producer countries. Workers often enter the trade from a metalworking background, or after experience with the stage, theater, or some other aspect of show business. Even within the pyrotechnic industry itself no formal apprenticeship programs are offered. Personnel with metalworking skills, including machinists and toolmakers, together with others conversant with the natural sciences, constitute the working body of pyrotechnists. A typical fireworks manufacturer, which may be a division of an arms supplier, supports 200 – 500 employees and has annual sales of $30 - 100 \times 10^6$ DM (1990).

These enterprises manufacture small fireworks and pyrotechnic devices for maritime signaling; for military illumination, signaling, simulation, training, and smoke concealment; and for industrial applications (e.g., gas generators in air bags and belt tighteners, actuators, and starter mixtures for polymerizations in the chemical industry). Other products include pyrotechnic components for primers and munitions (delay elements, ejectors, bursting charges, and tracers) and munitions designed specifically for police use (e.g., stun grenades and tear gas cartridges).

As a result of political developments during the 1980s, American and European pyrotechnic companies with military product lines have also become engaged in the dismantling of enormous quantities of munitions, including pyrotechnic devices. Disposing of these materials in accordance with environmental regulations imposes severe technical demands on the pyrotechnic industry, especially with respect to technologies for the incineration of explosive wastes and associated off-gas control.

7. Legal Aspects; Storage and Transportation

The dangers inherent in all aspects of pyrotechnics – including production, storage, transport, sale, and use – have resulted in a wide range of legal restrictions throughout the world.

Pyrotechnics manufacturers as well as those engaged in the sale of pyrotechnic products must obtain government licenses for both plants and warehouses. Provisions regarding the distribution of fireworks vary greatly from country to country, and will not be covered here in detail. All share the common goal of exerting some measure of control over the way fireworks are sold and utilized to minimize potential danger and disturbance of the general public. Sales to young people are generally prohibited, and even adults are often permitted to acquire only certain types of fireworks for display at certain times.

The purchase of pyrotechnic products for industrial purposes and of pyrotechnic munitions (e.g., emergency flares) is similarly governed by restrictions.

Figure 12. Subcaliber demonstration cartridge for a mortar a) Priming cap; b) Sabot "dummy" ejection charge; c) Propellant charge; d) Cartridge; e) Stabilizing fins; f) Flash/smoke charge; g) Impact fuse

The transport of dangerous goods has long been the subject of a consistent set of inter-

national regulations. Most pyrotechnic goods fall into Class 1 as defined by recommendations from the Committee of Experts on the Transport of Dangerous Goods of the United Nations Economic and Social Council (ECOSOC). These recommendations in turn form the basis for nearly all important national and international transport regulations [11]. Class 1 includes all explosives, as well as items containing explosives, and thus essentially all pyrotechnic materials. Class 1 is subdivided into five divisions based on the nature of the potential hazard posed by a particular substance or product. The classification criteria themselves were also defined by the United Nations, and have been recommended for international use [12]. The five categories of explosives follow [11]:

Division 1.1. Substances and articles that create a mass explosion hazard (where a mass explosion is one that affects almost the entire load virtually instantaneously).

Division 1.2. Substances and articles that constitute a projection hazard, but not a mass explosion hazard.

Division 1.3. Substances and articles that present a fire hazard and either a minor blast hazard or a minor projection hazard or both, but not a mass explosion hazard. This division comprises substances and articles which (1) give rise to considerable heat, or (2) burn one after another, producing minor blast and/or projection effects.

Division 1.4. Substances and articles which present no significant hazard. This division comprises substances and articles presenting only a small hazard in the event of ignition or initiation during transport. The effects are largely confined to the package, and no projection of fragments of appreciable size or range is to be expected. An external fire must not cause virtually instantaneous explosion of almost the entire contents of the package.

Division 1.5. Very insensitive substances that nevertheless present a mass explosion hazard (slurry explosives).

Because some substances and products are not mutually compatible from a safety or chemical standpoint, Class 1 is also divided into 12 "compatibility groups" to avoid problems that might arise through inappropriate packaging. These compatibility groups are identified by cap-ital letters. Black powder is listed among the explosives in Division 1.1 and has been allocated to compatibility group D. Most other pyrotechnic items fall into compatibility group G of Division 1.1 (e.g., display firework shells with flash compositions or large calibers), Division 1.3 (display fireworks of minor caliber, flares, and illuminating cartridges), and Division 1.4 (Category 2 fireworks, signal ammunition, smoke grenades).

Another hazard category with the compatibility designation S in Division 1.4 is defined by United Nation recommendations as follows: "Substances and articles of this division are in compatibility group S if they are so packaged or designed that any hazardous effects arising from accidental functioning are confined within the package unless the package has been degraded by fire, in which case all blast or projection effects are limited to the extent that they do not significantly hinder fire-fighting aids or other emergency response efforts in the immediate vicinity of the package." (For example, Category 1.4 S includes Category 1 fireworks, caps, and igniters.)

Assigning explosive substances and articles to explosion hazard groups has resulted in a broad international consensus with regard to assessment and classification, which now extends far beyond the transport sector alone. All Class 1 substances and articles now not only belong to designated hazard and compatibility groups, but they also carry internationally binding code numbers referred to as "UN numbers." For example, the designation "0333, Fireworks, 1.1 G" unambiguously identifies an article as fireworks that present a mass explosion hazard, and "0336, Fireworks, 1.4 G" indicates fireworks that present no special hazard. The codes can be used to find and classify the article in relevant transport regulations applicable to carriers of all types [13–16].

Efforts are being made to expand the application of these internationally accepted classifications and hazard descriptions to other aspects of handling explosive materials and devices, including production and storage. Thus, this system serves as a basis for classifying pyrotechnic

compositions, semifinished products, and articles under the accident prevention regulations of the German trade associations [17, 18]. It also applies to the assessment of hazards posed by the storage of explosives, devices containing explosives, and munitions [19]. The definitions are equivalent and often identical to those proposed by the United Nations.

A European project foresees complete uniformity in the description and distribution of pyrotechnic devices, specifically fireworks, and is an important step in the standardization of safety evaluation and technical characterization [20]. A similar standardization effort is ongoing in the United States and Canada. Virtually every European country classifies fireworks according to both structure and intended use, but with differing restrictions and regulations. Efforts toward standardization were initiated in 1990 in an attempt to establish a single set of generally applicable category definitions [21]:

Category 1. Fireworks which present a very low hazard and which are intended for use in confined areas, including fireworks which are intended for use inside domestic buildings

Category 2. Fireworks which present a low hazard and which are intended for outdoor use in confined areas

Category 3. Fireworks which present a medium hazard and which are intended for outdoor use in large, open areas

Category 4. Fireworks which present a high hazard or are unfinished, and which are intended for professional use only.

Pyrrole

Albrecht Ludwig Harreus, BASF Aktiengesellschaft, Ludwigshafen, Federal Republic of Germany

1. **Pyrrole** 1
2. **Pyrrole Derivatives** 2
3. **Toxicology and Occupational Health** . . 3
4. **References** 3

1. Pyrrole

Pyrrole[*109-97-7*],1*H*-pyrrole, azole, C_4H_5N, M_r 67.09, with its five-membered heterocyclic ring system has a fundamental role in the living world.

1 **2**

Pyrrole derivatives (cyclic tetrapyrroles) assume their most important role in respiration (hemoglobin, cytochromes) and photosynthesis (chlorophyll). Bile pigments are examples of natural linear tetrapyrroles. Low molecular mass pyrroles with antibiotic action have been isolated from microorganisms (pyrrolnitrin, → Antibiotics).

F. F. Runge detected pyrrole in 1834 as a constituent of coal tar. The very nonspecific reaction used for detection (red coloration of a spruce splint dampened with hydrochloric acid) gave pyrrole its name (Greek pyrros = fiery).

Physical Properties. Pyrrole, *mp* −23.4 °C, *bp* 130 °C (101.3 kPa), when freshly distilled, is a colorless liquid with a chloroform-like odor, which rapidly becomes brown in air and gradually resinifies. Pyrrole is hygroscopic, not very soluble in water (ca. 5 %), and miscible with most organic solvents. Further physical data are as follows:

Density d_4^{20}	0.9698
Refractive index n_D^{20}	1.5085
Viscosity (20 °C)	1.31 mPa · s
Flash point (DIN 51 755)	33 °C
Ignition temperature (DIN 51 794)	550 °C
Explosion limits	
lower	3.1 vol %
upper	14.8 vol %

The most important physical properties and spectroscopic data for pyrroles are summarized in [5].

The pronounced aromatic character of pyrrole is not consistent with the classical constitutional formula (**1**). The direction of the dipole moment, the bond lengths, and a very low basicity show that the free electron pair on nitrogen participates in the formation of an aromatic 6π-electron system, which is conveyed schematically by (**2**), whereas (**1**) represents only one of several possible mesomeric structures.

Chemical Properties. Pyrrole is unstable toward mineral acids, and is protonated in the 2-position. The resulting pyrrylium cation polymerizes very readily to give high molecular mass pyrrole resins (pyrrole red).

Because of its high π-electron density, the characteristic reactions of pyrrole are electrophilic substitutions. Substitution occurs preferentially in the 2-position. The reactions proceed under mild conditions, but must be adapted to the compound's sensitivity toward acid. Examples of electrophilic substitution include acetylation with acetic anhydride (which does not require a Friedel – Crafts catalyst), sulfonation with the SO_3– pyridine complex, nitration with acetyl nitrate (nitric acid/acetic anhydride), and halogenation with bromine, which leads directly to a tetrasubstituted product.

As a result of delocalization of the electron pair on the nitrogen, pyrrole is weakly acidic (pK_a ca. 17.5). Corresponding salts can be prepared with alkali metals in liquid ammonia or metal hydrides in inert solvents (e.g., tetrahydrofuran). These can be converted into *N*-alkylpyrroles by reaction with alkyl halides. Pyrryl potassium reacts with carbon dioxide to give the potassium salt of pyrrole-2- carboxylic acid.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_453

Pyrrole can be reduced catalytically (Pd, Pt, Rh, Ni) to pyrrolidine. With less reactive reducing agents (e.g., zinc in glacial acetic acid) the intermediate 3-pyrroline [*109-96-6*] (2,5-dihydropyrrole) can be obtained. This is the only one of the three dihydropyrroles that is somewhat stable.

Production and Use. Suitable processes for the industrial production of pyrrole include the reaction of furan (→ Furan and Derivatives) with ammonia over SiO_2/Al_2O_3 catalysts (zeolites) [6] and the catalytic dehydrogenation of pyrrolidine [*123-75-1*] [7].

The reaction of 2,5-dimethoxytetrahydrofuran with ammonia over zeolites [8] also leads to pyrrole, as does gas-phase cyclocondensation of butynediol with ammonia over an aluminum oxide/thorium oxide catalyst [9].

Mild steel drums lined with polyethylene are suitable as transport and storage vessels.

BASF and Shell produce pyrrole commercially, although its use remains limited. An electrically conducting polypyrrole is prepared from pyrrole by electrochemical polymerization, → Polymers, Electrically Conducting, Chap. 5.3. [10].

2. Pyrrole Derivatives

There are many possible synthetic routes to substituted pyrroles [11–13]. Of the classical syntheses of *C-substituted pyrroles*, the Knorr pyrrole synthesis (**3**) together with the Paal–Knorr (**4**) and Hantzsch syntheses (**5**) are particularly important. Appropriate α-aminoketones for the Knorr synthesis are usually generated in situ by reduction of the corresponding oximino compound, most frequently with zinc in acetic acid. The methylene group of the carbonyl compound has to be activated, therefore β-dicarbonyl compounds such as β-ketoesters and β-diketones are preferred.

N-Substituted pyrroles can easily be prepared industrially by dehydrogenation of the corresponding pyrrolidines. This reaction is carried out in the gas phase at 250–300 °C over such catalysts as Pd/Al_2O_3 or $Pd/MgO/Al_2O_3$ [7], [14]. Yields of *N*-alkylpyrroles surpass 90 %. Silicates are less suitable as carriers. *N*-Alkylpyrroles can also be produced by reaction of 2-butene-1,4-diol with amines in the gas phase (e.g., copper catalysts) [15].

Many *N*-alkyl and *N*-aryl pyrroles can be produced quite elegantly by reacting appropriate amines with 2,5-dialkoxytetrahydrofurans, in particular 2,5-dimethoxytetrahydrofuran [*696-59-3*][16],which is readily accessible industrially through electrooxidation of furan with subsequent hydrogenation [8], [11], [12], [17].

Special methods have been developed for the synthesis of *3-substituted pyrroles* [18].

3-Substituted 4-phenylpyrroles, such as fenpiclonil [*74738-17-3*] (Ciba-Geigy), display fungicidal properties, and are derived from the natural product pyrrolnitrin, → Fungicides, Agricultural [19].

Fenpiclonil

Derivatives of pyrrole-3,4-dicarboxylate esters show herbicidal activity [20], and those of 1-aryl-3- cyanopyrroles have insecticidal effects [21]. *N*-Methyl-2-pyrrylmethyl sulfides can be used as flavorings [22].

N-Methylpyrrole [*96-54-8*], 1-methylpyrrole, 1-methyl-1*H*-pyrrole, C_5H_7N, M_r 81.12, *mp* −57 °C, *bp* 112 – 113 °C (101.3 kPa), d_4^{20} 0.9088, n_D^{20} 1.4889, flash point 16 °C (DIN 51 755), ignition temperature 400 °C (DIN 51 794), is a bright yellow liquid that must be protected from light and air during storage. *N*-Methylpyrrole is miscible with almost all common organic solvents and ca. 1 % soluble in water.

N-Methylpyrrole is added as a stabilizer to chlorinated hydrocarbons [23]. It serves as starting material for the synthesis of 1-methylpyrrole-2-acetic acid and its derivatives, which are building blocks for many anti-inflammatory drugs, including tolmetin (Cilag), → Anti-inflammatory – Antirheumatic Drugs [24].

N-Methylpyrrole is produced commercially by BASF.

3. Toxicology and Occupational Health

Pyrrole is toxic if swallowed. The acute oral LD_{50} in rats is 137 mg/kg [25]. The acute intraperitoneal LD_{50} in mice is 98 mg/kg [26]. The subcutaneous LD_{50} in mice is 61 mg/kg [27]. Pyrrole does not cause skin irritation when applied to intact skin of white rabbits for up to 4 h, but it does cause significant ocular lesions, with a risk of serious permanent damage to the eyes. The LC_{50} is 2.27 mg/L (rat, inhalation, 4 h). Rats exposed to an atmosphere highly enriched or saturated with pyrrole at room temperature died after 30 min. Irritation of eye and nasal mucosa were observed after overexposure [25].

Pyrrole showed no mutagenic activity in the Ames test (with or without metabolic activation) [28–32]. Pyrrole did not induce DNA damage in a test with *Escherichia coli* [32] and also gave a negative result in the DNA-repair test in rat hepatocytes [33], [34]. Pyrrole had positive genotoxic activity in the rec-assay with *Bacillus subtilis*, and exhibited the ability to cleave DNA in lambda phages [35]. After intraperitoneal administration of pyrrole to mice, an epoxide was identified as a toxic metabolite in the lung. The enzyme involved was P450. Emphysema and bronchiolar necrosis were found in the animals [36], [37].

***N*-Methylpyrrole** is harmful if swallowed. The acute oral LD_{50} in rats is about 1400 mg/kg. The dermal LD_{50} in rabbits is > 400 mg/kg. The substance causes irritation of healthy intact or scarified skin in white rabbits when it is applied for up to 2 h, but it does not lead to significant ocular irritation. The LC_{50} in rats after inhalation for 1 and 4 h is greater than 22.4 and 5.6 mg/l, respectively; there was no mortality. Rats exposed to an atmosphere highly enriched or saturated with *N*-methylpyrrole at room temperature died after 1 h. Both severe irritation of the mucosa and narcotic effects were observed [38].

N-Methylpyrrole showed no mutagenic activity in the Ames test with or without addition of S-9 mix [28], [38]. It was positive in the rec-assay with *Bacillus subtilis* (± S-9 mix), and exhibited an ability to cleave DNA in lambda phages [35].

1. Introduction

Pyrrolidones became available industrially through the fundamental work of W. Reppe on acetylene chemistry. He synthesized butynediol and from it γ-butyrolactone, the starting material for the commercial production of pyrrolidones (→ Butyrolactone).

2. 2-Pyrrolidone

Physical Properties. 2-Pyrrolidone [*616-45-5*], pyrrolidone, 2-pyrrolidinone, γ-butyrolactam, C_4H_7NO, M_r 85.12, *mp* 25.57 °C, *bp* 245 °C (101.3 kPa), is a colorless, hygroscopic liquid above its melting point. It is miscible with water and common organic solvents, but not with aliphatic or cycloaliphatic hydrocarbons. Further physical data follow:

Density (30 °C)	1.103 g/cm^3
Refractive index n_D^{30}	1.484
Viscosity (30 °C)	10.2 mPa · s
Enthalpy of fusion	135 kJ/kg
Enthalpy of evaporation (40 °C)	666 kJ/kg
Dielectric constant (35 °C)	27.1
Dipole moment (30 °C, dioxane)	3.8 D
Flash point (DIN 51 758)	138 °C
Ignition temperature (DIN 51 794)	390 °C

Chemical Properties. 2-Pyrrolidone has amphoteric properties: it forms salts with hydrogen chloride, hydrogen bromide, and alkalis. It exhibits typical properties of primary lactams [1]. On heating with strong aqueous alkalis or mineral acids it is hydrolyzed to 4-aminobutyric acid [2]. The reactions at the lactam nitrogen are industrially the most important, in particular viny-lation (see Chap. 4). Alkali-metal salts of 2-pyrrolidone react with alkyl halides or sulfates to give the corresponding *N*-alkyl-2-pyrrolidones. *N*-Alkylation can also be achieved by treatment of 2-pyrrolidone with alcohols in the gas phase on alumina [3] or copper chromite catalysts [4]. *N*-Acylation can be readily achieved with carboxylic acid anhydrides or chlorides [2]. Noteworthy among the condensations with aldehydes are the reactions with formaldehyde to give *N*-hydroxymethyl-2-pyrrolidone [5] and with acetaldehyde to give *N*-(1-hydroxyethyl)-2-pyrrolidone [6, 7], which can be used to produce *N*-methyl- and *N*-vinyl-2-pyrrolidone, respectively. 2-Pyrrolidone polymerizes to a polyamide (nylon 4) in the presence of alkali and a carboxylic acid chloride catalyst (→ Fibers, 4. Synthetic Organic) [8].

Production. 2-Pyrrolidone can be produced by the following methods:

1) Catalytic [9] or electrochemical reduction [2] of succinimide
2) Carbonylation of allylamine [10]
3) Hydrogenation of succinic acid dinitrile under hydrolytic conditions [11]
4) Reaction of maleic or succinic anhydride in aqueous ammonia with Pd – Ru catalysts [12]

Industrially, 2-pyrrolidone is almost exclusively produced by reacting aqueous γ-butyrolactone [*96-48-0*] with ammonia [13]:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_457

Formation of the undesired 4-(*N*-2-pyrrolidonyl)butyramide can be suppressed if the twostage reaction is carried out in the gas phase on a magnesium silicate catalyst (250–290 °C, 0.4–1.4 MPa) [14].

Quality Specifications and Analysis. Technical-grade 2-pyrrolidone has a minimum content of 99.5 wt % (gas chromatography), and a maximum water content of 0.1 wt % (Karl Fischer titration).

Handling, Storage, and Transportation. 2-Pyrrolidone is transported in steel drums. Other materials suitable for storage and transportation are aluminum and stainless steel. Moisture must be excluded. 2-Pyrrolidone can be kept for ca. 1 year in closed containers. Yellowing does not affect the quality. 2-Pyrrolidone is not self-igniting or explosive, but is flammable.

Uses. Over 95 % of the 2-pyrrolidone produced is processed into *N*-vinyl-2-pyrrolidone. It is also used in the pharmaceutical industry for the production of pyrrolidone nootropics, especially piracetam (see 5). 2-Pyrrolidone is also used as a solvent and reaction medium since it is high boiling, inert, and noncorrosive. It can be used to decolorize kerosene and other hydrocarbons. Aromatic hydrocarbons can be extracted from petroleum with 2-pyrrolidone. In the polish and cleaning materials industry it is added to styrene–acrylate copolymer dispersions as a film-forming agent.

Economic Aspects. Worldwide demand for 2-pyrrolidone was 14 000 t in 1983 [15] and has since risen considerably. Important producers are BASF and GAF.

3. *N*-Methyl-2-pyrrolidone

N-Methyl-2-pyrrolidone (NMP) [*872-50-4*], *N*-methylpyrrolidone, 1-methyl-2-pyrrolidone, C_5H_9NO, M_r 99.13, is an important, versatile solvent and reaction medium for the chemical industry because of its favorable properties [16, 17].

Physical Properties. NMP, *mp* −24.4 °C, *bp* 204.3 °C (101.3 kPa), is a colorless liquid with a weakly aminelike odor; it is completely miscible with water and most common organic solvents. Further physical data follow:

bp (1.3 kPa)	81–82 °C
Density (25 °C)	1.028 g/cm^3
Refractive index n_D^{25}	1.469
Viscosity (20 °C)	1.796 mPa · s
Surface tension (25 °C)	0.041 N/m
$t_{crit.}$	451 °C
$p_{crit.}$	4.78 MPa

Vapor pressure

t, °C	40	60	80	100	150
p, kPa	0.134	0.459	1.33	3.37	21.9

Specific heat capacity

t, °C	0	25	50	100
c_p (liquid), kJ kg^{-1} K^{-1}	1.70	1.78	1.86	2.03

Enthalpy of evaporation (20 °C)	550 kJ/kg
Thermal conductivity (20 °C)	1.8 W m^{-1} K^{-1}
Dielectric constant (23 °C)	32
Dipole moment	4.09 D
Flash point (DIN 51 758)	91 °C
Ignition temperature (DIN 51 794)	245 °C
Lower explosion limit	1.3 vol %
Upper explosion limit	9.5 vol %

Chemical Properties. NMP is a very weak base and forms a solid hydrochloride with anhydrous hydrogen chloride. A 10 % aqueous solution has a pH of 7.7–8. NMP is chemically very stable. The lactam ring is only opened by strong aqueous acids and bases to give 4-methylaminobutyric acid. NMP has limited resistance toward oxygen. It is oxidized at the 5-position, after several intermediate stages *N*-methylsuccinimide is formed. This compound can also be produced directly from NMP, for example by oxidation with ruthenium tetroxide [18]. The carbonyl group of NMP reacts

with phosgene, phosphorus pentachloride, and other chlorinating agents. 2-Chloro-1-methyl-1-pyrrolidinium chloride [*15862-82-5*] can be readily produced with phosgene [19] and reacts with various nucleophiles (amines, alkoxides) [19,20]:

It can be used as a catalyst for the synthesis of carboxylic acid chlorides from carboxylic acids [19].

With strong bases (e.g., lithium diisopropylamide) NMP can be deprotonated in the 3-position to form amide enolates which can react with alkyl halides [21] and aryl bromides [22]. Condensations with esters at the CH_2 group in the 3-position are achieved in the presence of sodium ethoxide [23]. This route is also used in the Späth nicotine synthesis [24]. Numerous catalytic effects can be obtained with NMP as the reaction medium. For example, certain acetylides can only be alkylated in NMP [25]; ethylene glycol can only be produced from synthesis gas on rhodium carbonyls when NMP is used as the reaction medium [26].

Production. Large-scale production of NMP is predominantly carried out by reacting γ-butyrolactone with methylamine in a shaft reactor (high-pressure tube with special baffles) at 200–350 °C and ca. 10 MPa.

Other processes also analogous to those used for pyrrolidone synthesis can also be used, in particular hydrogenation of *N*-methylsuccinimide or mixtures of maleic or succinic anhydride and methylamine [27]. NMP can also be produced by hydrogenation of *N*-hydroxymethyl-2-pyrrolidone (see page 2) [28] or by reaction of acrylonitrile with methylamine in the presence of a peroxide radical initiator [29].

Quality Specifications and Analysis. Technical-grade NMP has the following specifications (gas chromatography): NMP content, min. 99.5 wt %; methylamine, max. 0.02 wt %; water, max. 0.1 wt % (Karl Fischer titration); color index, APHA 50 max. For special areas of use (e.g., electronics) higher purities are supplied with the following specifications: methylamine, max. 0.01 wt %; water, max. 0.05 wt %.

Handling, Storage, and Transportation. NMP is transported in tank cars or trailers and in drums. Transport and storage containers are generally made of mild steel. Stainless steel, nickel, and aluminum are also suitable as container and drum materials. Small quantities can be stored in polyethylene, polypropylene, or clear glass bottles. NMP shows unlimited shelf life in tightly closed containers, slight discoloration does not impair its quality. It is flammable.

Uses. NMP is an important solvent because of its low volatility, thermal stability, high polarity, and aprotic, noncorrosive properties. Its favorable toxicological and ecological properties account for the fact that NMP is replacing other solvents such as chlorinated hydrocarbons.

The most important areas of use are:

1) *Petrochemical processing*: acetylene recovery from cracked gas, extraction of aromatics and butadiene, gas purification (removal of CO_2 and H_2S), lube oil extraction
2) *Engineering plastics*: reaction medium for the production of high-temperature polymers such as polyethersulfones, polyamideimides, and polyaramids
3) *Coatings*: solvent for acrylic and epoxy resins, polyurethane paints, waterborne paints or finishes, printing inks, synthesis/diluent of wire enamels, coalescing agent
4) *Agricultural chemicals*: solvent and/or cosolvent for liquid formulations
5) *Electronics*: cleaning agent for silicon wafers, photoresist stripper, auxiliary in printed circuit board technology
6) *Industrial and domestic cleaning*: component in paint strippers and degreasers e.g., removal of oil, fat, and soot from metal surfaces, carbon deposits and other tarry polymeric residues in combustion engines

Economic Aspects. World production of NMP is currently estimated at 20 000–30 000 t/a. The most important producers are BASF and GAF.

Environmental Aspects. NMP is nontoxic to most aquatic life and shows good biodegradability [16,30]. The most important data are:

BOD_5 1100 mg/g NMP (DIN 38 409 part 51), COD 1600 mg/g NMP (DIN 38 409 part 41), TOC (total organic carbon) 600 mg/g NMP (DIN 38 409 part 3), biodegradability: > 90 % DOC (dissolved organic carbon) degradation (Zahn-Wellens static test, DIN 38 412 part 25).

4. *N*-Vinyl-2-pyrrolidone

Physical Properties. *N*-Vinyl-2-pyrrolidone (NVP) [*88-12-0*], *N*-vinylpyrrolidone, 1-vinyl-2-pyrrolidone, 1-ethenyl-2-pyrrolidinone, C_6H_9NO, M_r 114.14, is a colorless to yellowish liquid when freshly distilled, with a characteristic odor, *mp* 13.5 °C, *bp* 90 – 92 °C (1.3 kPa). It is completely miscible with water and most organic solvents, but only partially miscible with aliphatic hydrocarbons. Further physical constants follow:

Density (20 °C)	1.043 g/cm^3
Refractive index n_D^{20}	1.514
Viscosity (20 °C)	2.4 mPa · s
Vapor pressure (20 °C)	0.012 kPa
Flash point (DIN 51 758)	95 °C
Ignition temperature (DIN 51 794)	240 °C
Lower explosion limit	1.4 vol %
Upper explosion limit	10 vol %

Chemical Properties. NVP is stable toward alkalis at room temperature. Above 0 °C it is cleaved by aqueous mineral acids into acetaldehyde and 2-pyrrolidone; the latter reacts with an excess of NVP to give 1,1′-ethylidene-bis-2-pyrrolidone [31]. Protic compounds such as amides, thiols, alcohols, and phenols add to the double bond according to the Markovnikov rule, for example, *N*-(1-phenoxyethyl)-2-pyrrolidone is formed with phenol [32, 33]. Catalytic hydrogenation produces *N*-ethyl-2-pyrrolidone. Hydroformylation on rhodium catalysts forms 2-*N*-(2-pyrrolidonyl)propanal as the major product [34]. On prolonged standing, particularly in warm conditions, NVP tends to polymerize. Industrially, NVP is converted into polyvinylpyrrolidone using radical initiators.

Production. Industrially, NVP is produced by reacting 2-pyrrolidone with acetylene in high-pressure autoclaves at 130 – 160 °C and pressures of up to 2.6 MPa [32, 33, 35]. Vinylation proceeds in the liquid phase and is catalyzed by 2-pyrrolidone – potassium, which is obtained by dissolving 1 – 5 % potassium hydroxide (the water formed is removed by distillation in vacuo) or potassium in 2-pyrrolidone. To avoid the danger of explosions acetylene – nitrogen mixtures are used instead of acetylene. The crude product obtained by continuous or batch production is purified by vacuum distillation. Leading producers are BASF and GAF.

Other methods such as the elimination of *N*-(1-hydroxyethyl)- (see page 2) and *N*-(1-alkoxyethyl)-2-pyrrolidones are not industrially important [6, 7, 33].

Quality Specifications and Analysis. Composition is determined by gas chromatography and water is titrated with the Karl Fischer reagent. A typical commercial product has the following composition: NVP content, min. 99 wt %; 2-pyrrolidone, max. 0.2 wt %; water, max. 0.1 wt %; color index (freshly filled, APHA), 40 max.; stabilizers: 10 ppm *N,N′*-bis(1-methylpropyl)-1,4-benzenediamine or 0.1 wt % sodium hydroxide.

Handling, Storage, and Transportation. NVP must be protected from heat and direct sunlight. Even in closed containers NVP can only be stored for a limited period because it tends to polymerize. Stabilizers are therefore added. *N,N′*-Bis(1-methylpropyl)-1,4-benzenediamine [*101-96-2*] is an important, NVP-soluble stabilizer that does not interfere with further processing. Use of this stabilizer allows the product to be stored for ca. 300 d at 20 °C, and ca. 150 d at 25 °C. Stabilization with solid sodium hydroxide that can be easily filtered off, is not as efficient. Storage at temperatures close to the melting point results in separation of NVP from the stabilizer due to repeated solidification and melting. This shortens the shelf life considerably and can lead to uncontrolled polymerization. Solidified NVP must therefore be melted carefully in a water bath (max. 40 °C) or at room temperature (max. 30 °C) and homogenized by continuous agitation. NVP is flammable.

Uses. NVP is an important precursor and intermediate for process auxiliaries and additives. The main areas of use are the production of polyvinylpyrrolidone and copolymers (→ Polyvinyl Compounds, Others, Chap. 3.1.), the preferred comonomers being vinyl acetate and methyl acrylate. Ca. 10 – 15 % of the monomer is used in the pharmaceutical industry for the production of a polyvinylpyrrolidone – iodine complex used as a disinfectant. NVP is also used as a reactive solvent for UV-curable resins for the production of printing inks and paints as paper and textile auxiliaries, and as an additive in the cosmetics industry.

5. Other Pyrrolidone Derivatives

For certain areas of application special *N*- or *C*-substituted 2-pyrrolidones have been developed, whose physiochemical properties are especially adapted for a specific use. For example, *N*-ethyl-2-pyrrolidone [*2687-91-4*] is used as a reaction medium for low- and high-temperature reactions; *N*-(2-hydroxyethyl)-2-pyrrolidone [*3445-11-2*] is used in the electronics industry, *N*-octyl- [*2687-94-7*] and *N*-dodecyl-2-pyrrolidone [*2687-96-9*] serve as formulation auxiliaries for triazole fungicides [36]. *N*-(2-Aminoethyl)-2-pyrrolidone [*24935-08-8*] derivatives are used as solubilizing and complexing aids [37]. A range of nootropic pharmaceuticals (e.g., piracetam [*7491-74-9*] **1**) are *N*-substituted 2-pyrrolidones [38]. *N*-1-(3-Trifluoromethylphenyl)-2-pyrrolidone derivatives (e.g., fluorochloridone [*61213-25-0*] **2**) are used as herbicides [39].

6. Toxicology and Occupational Health

2-Pyrrolidone does not have a particularly high acute toxicity: LD_{50} values are > 3.2 g/kg – ca. 8.5 mL/kg (rat, oral); 3.2 g/kg – 5.8 mL/kg (mouse, oral); 6.5 mL/kg (guinea pig, oral); 3 g/kg (rat, i.p.); 3.7 g/kg (mouse, i.p.); 3 g/kg (mouse, i.v.) [40–46]. In rabbits it is only mildly irritating to intact skin, if at all, and not irritating to the eyes [41,42]; in another study clouding of the cornea has, however, been reported [43]. In guinea pigs the compound causes severe skin irritation but no sensitization [40]. It can be absorbed through the skin and causes death in rats (ca. 2 mL/kg) [41]. Inhalation (8 h) of air saturated with 2-pyrrolidone at 30 °C produced no symptoms in rats [41]. In a 13-d study a slight increase in the mean relative kidney weight was observed in rats fed with 10 g/kg [40]. 2-Pyrrolidone did not produce mutagenicity in the Ames test (± S-9 mix) [41] but induced aneuploidy in *Saccharomyces cerevisiae* [46]. It is nonteratogenic in mice (oral, i.p.) and rats (oral) [40,41].

2-Pyrrolidone has been identified as an endogenous component in the blood plasma of rats, mice, and humans; it is metabolized to 4-aminobutanoic acid and other compounds (e.g., succinimide) [47].

2-Pyrrolidone possesses psychotropic properties resembling those of tranquilizing drugs in mice, rabbits, rats, cats, and pigeons. It is said to have irritating properties to human skin [40].

***N*-Methylpyrrolidone** is only slightly toxic if ingested or inhaled. LD_{50} values are 3.5 mL/kg –4.3 g/kg (rat, oral); 7.5 mL/kg (mouse, oral); 3.5 g/kg (rabbit, oral); 2.2 mL/kg (rat, i.v.); 2.4 mL/kg (rat, i.p.); 1.9 mL/kg (mouse, i.p.), > 2.5 g/kg (rat, percutaneous); 4 – 8 g/kg (rabbit, percutaneous). Inhalation (6 – 8 h) of a highly enriched or saturated atmosphere at 20 or 50 °C produced no symptoms in cats, mice, rats, rabbits, or guinea pigs. The LC_{50} value is > 5.1 mg/L (rat, inhalation, aerosol, 4 h) [16,48].

In rabbits, NMP produced slight skin irritation (method according to Draize); undiluted it caused moderate reddening and scaling after short exposure (5 – 15 min), 20-h exposure led to additional edema. In the rabbit eye it caused conjunctivities, redness, and reversible clouding of the cornea. NMP is not a skin sensitizer in guinea pigs [16,48].

Rabbits administered NMP by gavage in doses of 0.4 mL kg^{-1} d^{-1} (5 times/week for

5 weeks) showed no adverse effects, yet death occurred at 1 and 2 mL kg^{-1} d^{-1}. Cats were less sensitive. In rats, 0.25 mL kg^{-1} d^{-1} (4 weeks) caused no effects; 0.5 and 1 mL kg^{-1} d^{-1} led to slightly retarded body weight gain in males. A slight decrease in leucocytes was observed at 1 mL kg^{-1} d^{-1}; 2 mL kg^{-1} d^{-1} retarded body weight gain and led to a decrease in leucocytes and testicular damage. In a 90-d study on rats, 2.5 g/kg feed caused no changes; 5 g/kg increased thyroid gland weight. Dermal application (20 d, 0.4 and 0.8 mL kg^{-1} d^{-1}) to intact or abraded skin of rabbits produced slight local irritation.

Inhalation (17 exposures, 6 h/d, 5 d/week) of a saturated or highly enriched atmosphere produced no symptoms in cats, rabbits, guinea pigs, or rats, but caused death in mice. In a 6-week study (6 h/d, 5 d/week) air saturated at 25 °C caused no symptoms in rats. In a 4-week inhalation study (whole body exposure, 6 h/d, 5 d/week), 0.1 and 0.5 mg/L were tolerated whereas 1 mg/L caused lethality through additional dermal and oral absorption. In another study (head – nose exposure), no symptoms could be detected (0.9 mg/L, 6 h/d, 10 d) [16,48].

NMP was found to be nonteratogenic in rats (oral, dermal, and inhalative) and mice (i.p., oral) in doses that were not maternally toxic[16, 48]. In several mutagenicity tests NMP did not demonstrate a genotoxic potential. It induced aneuploidy in *Saccharomyces cerevisiae*, but neither spindle disfunction nor chromosome damage was found in mice [16]. NMP was not carcinogenic in a 2-year inhalation study on rats (0.04 and 0.4 mg/L, 6 h/d, 5 d/week) [16].

NMP is rapidly absorbed and is mainly excreted in the urine within 24 h (rats, i.v.), excretory half-life 2.3 h. It is metabolized into three compounds, mainly 4-methylaminobutanoic acid [49].

The MAK value is 100 ppm (8 h) [48]. Additional information on toxicity is given in [16, 48].

***N*-Vinyl-2-pyrrolidone** exhibits moderate acute toxicity if ingested, inhaled, or administered intraperitoneally or intravenously. The LD_{50} values are > 0.8 – 2.5 g/kg (rat, oral); 0.9 g/kg (mouse, oral); ca. 0.3 – 0.47 g/kg (mouse, i.v.); > 0.25 – 0.605 g/kg (mouse, i.p.); 1 – 4 mL/kg (rat, dermal). The LC_{50} is > 3.7 mg/L (rat, cat, rabbit, mouse, guinea pig, inhalation, 6 h) [41,50]. NVP induces narcotic symptoms, irritation of the skin and eye, and damage to the liver, spleen, and kidneys. In rabbits, it is a mild irritant to intact skin; the undiluted compound causes redness, edema, and clouding of the cornea that lasts for more than 8 days. Inhalation (8 h) of air saturated with NVP at room temperature produced slight irritation of the mucosa. Repeated oral administration of NVP (drinking water or by gavage) caused liver damage in rats. Signs of liver damage were recorded for rabbits and cats. Intraperitoneal administration (5 d, 0.1, 0.25 mL/kg) caused death in mice but not in rats [41,50].

Inhalation of NVP vapor (up to 15 days, 6 h/d, 180 ppm) caused death of mice, cats, and rabbits but not of rats and guinea pigs. Damage to the liver was seen in mice and cats. Inhalative exposure of rats to the aerosol (0.3 – 0.75 mL/kg, 4 h/d, 5 d/week for 4 weeks) or vapor (1 – 120 ppm, 6 h/d, 5 d/week for 3 months) caused damage to the nasal mucous membranes and adenoids above 0.75 mL/L (5 ppm) and foci and areas of cellular alterations in the liver above 15 ppm. 120 ppm caused premature death. In the Syrian gold hamster (45 ppm, 6 h/d, 5 d/week for 7 weeks to 3 months) symptoms of irritation were seen in the upper respiratory tract [41, 50].

Slight signs of liver toxicity but no carcinogenic impairment of the liver was noted. In several tests NVP did not show mutagenic or clastogenic activity. In a 2-year inhalation study in rats (5, 10, and 20 ppm, 6 h/d, 5 d/week) carcinomas of the liver, adenomas, and adenocarcinomas of the nasal cavity were observed. Squamatous carcinomas of the larynx were reported at 20 ppm [41,50].

A single intravenous dose of ^{14}C-NVP is quickly metabolized and eliminated (mainly in the urine) in the rat. The plasma half-life is 1.9 h [51].

Epidemiological studies in humans revealed no adverse effects [52]. An MAK value cannot be defined on account of the carcinogenic potential. Additional information on toxicity is given in [50].

1. Quinoline

Quinoline was discovered in coal tar by F. F. RUNGE in 1834.

Quinoline

1.1. Properties

Quinoline [*91-22-5*], C_9H_7N, M_r 129.16, *mp* − 15.6 °C, *bp* 238 °C (101.3 kPa), d^{20} 1.0929, n_D^{20} 1.6268, specific heat (17 °C) 1.516 kJ/kg, heat of vaporization 367.6 kJ/kg, heat of combustion (25 °C) 36.4 MJ/kg, is a colorless liquid with characteristic odor. It is sparingly soluble in cold water, readily soluble in hot water, miscible with many organic solvents, and volatile in steam.

Quinoline is a weak tertiary base. With strong acids, it forms readily crystallizable salts; with alkyl halides and dialkyl sulfates, it forms quaternary addition compounds. Halogenation gives preferably the 3-substituted product; nitration, the 5- and 8-substituted products; and sulfonation, the 6- or 8-substituted products, depending on reaction conditions. Quinoline is catalytically hydrogenated to 1,2,3,4- or 5,6,7,8-tetrahydroquinoline, and further to decahydroquinoline. Oxidation leads to quinoline *N*- oxide, 2-quinolinol or 2-quinolinone, quinolinic acid (pyridine-2,3-dicarboxylic acid), or nicotinic acid, depending on the oxidizing agent used and the reaction conditions. Biochemical oxidation yields 2-oxoquinoline as the primary metabolite, which is then hydroxylated in the 6- or 8-position [5]. Reaction with sodium amide or ammonia in the presence of a Raney nickel catalyst gives 2-aminoquinoline.

1.2. Production

High-temperature coal tar contains an average of 0.3 % quinoline. Quinoline, together with isoquinoline and 2-methylquinoline, is recovered from the methylnaphthalene fraction of coal tar by extraction with sulfuric acid, followed by precipitation with ammonia. Then quinoline is separated from isoquinoline (*bp* 6 °C higher) by rectification of the crude base mixture (quinoline bases). It can be purified further by several processes, for example, selective oxidation, treatment with alkali, resinification of the byproducts with formaldehyde, or formation of the hydrate (in contrast to isoquinoline) [6]. Quinoline can also be obtained from the methylnaphthalene fraction by azeotropic distillation with ethylene glycol or diethylene glycol, and subsequent distillation [7].

Quinoline can be synthesized via the Skraup method by heating aniline and glycerol with sulfuric acid in the presence of a dehydrogenating agent (→ Amines, Aromatic, Chap. 2.2.4.), catalytic gas-phase reaction of aniline and acetaldehyde with formaldehyde – methanol [8], dehydrogenative cyclization of *N*-propylaniline in the gas phase [9], or pyrolysis of *N,N′*-diphenyl-1,1-propanediamine [10]. However, these syntheses are not yet industrially important because sufficient quantities of quinoline can be recovered from coal tar.

1.3. Uses and Economic Aspects

World production of quinoline is more than 2000 t/a. The main application of quinoline is the production of 8-quinolinol, which is obtained by alkali fusion of quinoline-8-sulfonic acid [*85-48-3*]. In addition, quinoline is used in the production of pyridine-2,3-dicarboxylic acid [*89-00-9*] (quinolinic acid) by oxidation [11]. Quinolinic acid is used to manufacture the herbicide Assert [*81405-85-8*] (imazapyr) [12]. Quinoline can be used to produce methine dyes (cyanines) (→ Methine Dyes and Pigments, Chap. 7.4.2.) and nicotinic acid [*59-67-6*] (via quinolinic acid).

Hydroquinolines can be employed as intermediates for pharmaceuticals such as antibiotics [13]. From quinoline, 4,5-dihydroimidazo[1,2-*a*]- quinoline-1-acetamides can be prepared as anticonvulsants, sedatives, and anxiolytics [14]. Quinoline can act as catalyst in the preparation of pharmaceuticals such as pyridazinone antihypertensives [15]. Fungicides can be obtained from 2-anilinoquinolines (from 2-aminoquinoline) [16]. Derivatives of 2-quinolinone [*59-31-4*] (carbostyril, prepared by oxidation of quinoline with hypochlorous acid, or selective, enzymatic hydroxylation of quinoline [17]) can be used as pharmaceuticals (e.g., cardiotonic drugs or antihistaminics) [18]. Quinoline alone, or as a mixture with isoquinoline and quinoline homologues, is an excellent solvent and extractant, especially for polycyclic aromatic compounds. Quinoline bases serve as acid-binding agents, corrosion inhibitors, or pickling inhibitors.

1.4. Derivatives

2-Methylquinoline [*91-63-4*], quinaldine, $C_{10}H_9N$, M_r 143.19, *bp* 247.6 °C (101.3 kPa), *mp* −2 °C, d^{20} 1.0582, n_D^{20} 1.6116, is a colorless liq-uid with a weak quinoline-like odor. It is soluble in organic solvents and very slightly soluble in water.

2-Methylquinoline

High-temperature coal tar contains an average of 0.2 % quinaldine. It is recovered from the quinoline base mixture by rectification and hydration. Quinaldine can be synthesized by the Skraup method from aniline and crotonaldehyde with sulfuric acid in the presence of a dehydrogenating agent.

Quinaldine is used for the synthesis of several dyes such as the trimethinecyanine dye pinacyanol [*605-91-4*] and the corresponding vinylogous dye (→ Methine Dyes and Pigments, Chap. 7.2.2.→ Methine Dyes and Pigments, Chap. 7.4.), the quinophthalone dye quinoline yellow [*8004-92-0*], and the indicator dye quinaldine red [*117-92-0*].

4-Methylquinoline [*491-35-0*], lepidine, $C_{10}H_9N$, M_r 143.19, *bp* 265.6 °C (101.3 kPa), *mp* 8 °C, d^{20} 1.0868, n_D^{20} 1.6200, is a colorless liquid with a weak quinoline-like odor. It is slightly soluble in water, miscible with many organic solvents, and volatile in steam.

4-Methylquinoline

4-Methylquinoline can be recovered from the highest-boiling fraction of the coal-tar quinoline bases via its *o*- cresol addition compound. It can be synthesized by condensation of aniline and methyl vinyl ketone [19].

4-Methylquinoline is used for the synthesis of several cyanine dyes (→ Methine Dyes and Pigments, Chap. 7.2.2.,→ Methine Dyes and Pigments, Chap. 7.4.4.).

8-Quinolinol [*148-24-3*], 8-hydroxyquinoline, oxine, C_9H_7ON, M_r 145.15, *bp* 266.6 °C (100.2 kPa), *mp* 75.8 °C, forms colorless crystals with a phenolic odor. It is readily soluble in ethanol, benzene, and chloroform; soluble in acetone, alkali, and acid; slightly soluble in diethyl ether; and very slightly soluble in water.

8-Quinolinol

8-Quinolinol is produced by alkali fusion of quinoline-8-sulfonic acid or synthesized via the

Skraup method by heating *o*-aminophenol (via benzoxazolone [20]) with *o*-nitrophenol, glycerol, and sulfuric acid.

8-Quinolinol and its salts with bivalent metals or mineral acids are used as fungicidal, bactericidal, insecticidal, and algicidal agents in crop protection products and disinfectants, as well as in preservatives for leather, textiles, plastics, coatings, paper pulp, and seeds. Several halogenated derivatives of 8-quinolinol show, in addition to a general antiseptic activity (→ Dermatotherapeutic Agents, Chap. 3.4.), a specific activity against amoebas (→ Chemotherapeutics, Chap. 3.5.2.). In azo dyes 8-quinolinol can serve as a heterocyclic coupling component. 8-Quinolinol, its dibrominated derivative Bromoxine [*521-74-4*], and the thiol analogue Thiooxine [*491-33-8*] are analytical reagents for the detection of numerous metals (→ Indicator Reagents).

2. Isoquinoline

Isoquinoline was discovered in coal tar by S. Hoogewerff and W. A. van Dorp in 1885.

Isoquinoline

2.1. Properties

Isoquinoline [*119-65-3*], C_9H_7N, M_r 129.16, *mp* 26.5 °C, *bp* 243.25 °C (101.3 kPa), d^{20} 1.0986, n_D^{20} 1.6148, specific heat 1.507 kJ/kg, heat of fusion 57.8 kJ/kg, heat of vaporization 379.3 kJ/kg, heat of combustion (25 °C) 36.45 MJ/kg, is a colorless, hygroscopic liquid that forms crystals on solidifying, with an odor resembling that of benzaldehyde. It is very slightly soluble in water, but miscible with many organic solvents.

Isoquinoline is a stronger base than quinoline. It forms readily crystallizable salts and quaternary addition compounds. Catalytic hydrogenation leads to 1,2,3,4- or 5,6,7,8-tetrahydroisoquinoline and further to decahydroisoquinoline. Oxidation in the liquid or vapor phase gives a mixture of nicotinic and isonicotinic acids (via pyridine-3,4-dicarboxylic acid by decarboxylation), whereas oxidation with peroxyacids gives isoquinoline *N*-oxide.

2.2. Production

High-temperature coal tar contains an average of 0.2 % isoquinoline. It is separated by distillation from the lower-boiling quinoline and the higher-boiling 2-methylquinoline of the quinoline base mixture. Further refining is based on the fact that isoquinoline, in contrast to quinoline and 2-methylquinoline, cannot be hydrated but can be crystallized at low temperature.

Isoquinoline can by synthesized, for example, via the Bischler – Napieralski reaction by cyclodehydration of *N*-acyl derivatives of β-phenylethylamine with Lewis acids and subsequent dehydrogenation.

2.3. Uses

Isoquinoline is used predominantly in the production of pharmaceuticals such as the anthelmintic praziquantel [*55268-74-1*] (→ Anthelmintics). Isoquinoline and hydroisoquinolines can also be used as intermediates for fungicides [21] and dyes (e.g., isoquinoline red [*6359-40-6*]).

3. Toxicology

The oral LD_{50} of quinoline in rats is 270 – 460 mg/kg [22], [23]; the dermal LD_{50} is 1400 mg/kg in rats [24], and ca. 600 mg/kg in rabbits [23]. Inhalation of air saturated with quinoline for 7 h caused death of almost all rats [25]. Acute symptoms were unspecific: the rats exposed showed piloerection, ataxia, and lack of motility. Dissection revealed hemorrhaging and cellular edema in the gastrointestinal tract, liver, and lung. The 24-h exposure of the skin of rabbits caused slight to moderate, but reversible, edema and erythema; after exposure of the eyes of rabbits, slight to moderate, but reversible, irritation was found [26]. After resorption in mammals, quinoline is excreted rapidly after hydroxylation and conjugation [27], [28].

Long-term feeding (0.05 – 0.25 % in the diet for 20 – 40 weeks) led to hepatocellular carcinomas and hemangiosarcomas in rats and mice [29], [30], but not in hamsters and guinea pigs [30]. When low doses (1.75 µmol per animal) were injected intraperitoneally into newborn mice on the first, eighth, and fifteenth day after birth, liver tumors were found 52 weeks after treatment [31]. Quinoline showed tumor-initiating activity on mouse skin at an effective total dose of > 2 mg per animal [32], which is ca. 250 – 300 times higher than the dose of benzo[*a*]pyrene required to obtain the same tumor incidence. Quinoline has toxic effects on aquatic life, with fish apparently being more sensitive than the aquatic invertebrates and algae tested; e.g., 5 mg/L was lethal to trout after 14 h and bluegill sunfish after 4 h [33], whereas toxic effects on daphnia were noticeable only above 50 mg/L [34]. The compound is readily degraded under natural conditions.

The oral LD_{50} of 2-methylquinoline (quinaldine) is 1230 mg/kg in rats [23], and the LD_{50} (i.p.) of 4-methylquinoline (lepidine) is 270 mg/kg in rats [35]. 4-Methylquinoline was found to be a tumor initiator on mouse skin, whereas 2-methylquinoline was not [32]. 4-Methylquinoline is tumorigenic when injected into newborn mice [31]. 2-Methylquinoline showed very weak mutagenicity with *Salmonella typhimurium* TA 100 [36], whereas the number of his-revertants was greater for 4-methylquinoline than for quinoline [37].

For 8-quinolinol an oral LD_{50} of 1200 mg/kg in rats and an i.p. LD_{50} of 48 mg/kg in mice are reported [38]. After i.p. injection of 100 mg/kg into mice, many died after several hours, whereas the same dose of quinoline caused no deaths [39]. In plant chromosomal studies, 8-quinolinol was found to act as a spindle inhibitor [40]. In two rodent studies by the U.S. National Toxicological Program, 8-quinolinol was classified as noncarcinogenic [40], [41] but was found to be mutagenic in the Ames test [42], [43], genotoxic in several other in vitro assays, and positive in the micronucleus assay [39].

The oral LD_{50} of isoquinoline is 360 mg/kg [23]. Isoquinoline shows no tumor-initiating activity [44] and proved to be nonmutagenic in the Ames test [37].

1. Radiation-Induced Polymerization

1.1. Polymerization by Ionizing Radiation

1.1.1. Initiation of Polymerization by Ionizing Radiation

When electrons, positrons, ions, gamma quanta, or X-rays with typical energies in the keV and MeV range are absorbed in solids, liquids, or gases, secondary electrons are produced in the energy degradation process. These enter into a Coulomb interaction with the atoms or molecules of the absorbers, which results in the formation of ions, electrons, and excited atoms or molecules [23–26].

As a direct consequence of the ionization process, the first species formed are cation–electron pairs with widely varying distances between the partners. The closer together they are, the stronger the Coulomb attraction between cation and electron.

Diffusional motion in liquids prevents complete recombination of the ion pairs. In liquid alkanes, for example, only a few percent of the ions initially formed with a *G* value (i.e., the amount of transformed molecules per 100 eV of absorbed energy) of ca. 4 escape ion pair recombination [27], [28].

When polymerization processes are initiated by ionizing radiation (radiation-induced polymerization), both the action of ions in pairs and that of "free" particles are important.

Another feature of radiation-induced polymerization is the possible simultaneous production of radical ions and free radicals that can initiate polymerization. Elementary reactions preceding the initiation of radiation-induced polymerization have been studied chiefly by pulse radiolysis [25], [28], [29–31]. Some reaction mechanisms are schematically illustrated in Figure 1.

When alkyl chlorides are irradiated (Fig. 1 A), the electron produced in the primary ion pair $RCl^+ \ldots + e_s^-$ is converted to unreactive chloride ion by dissociative electron capture, while the primary radical cation RCl^+ transfers its charge to the monomer M. If the monomer concentration is sufficiently high, the formation of a dimeric cation MM^+ and thus the initiation of the ionic polymerization chain reaction can be observed.

Reactions between solvated electrons e_s^- and monomers can be investigated in ethers such as tetrahydrofuran or dioxane (Fig. 1 B). In this case the primary radical cation RH^+ is very rapidly converted to the unreactive RH_2^+. If a monomer with sufficiently high electron affinity (styrene, acrylate) is added, a radical anion is formed; it is mainly converted by protonation into a free radical $(MH)^\bullet$. The formation of a dimeric anion MH^- is less probable.

Figure 1 C summarizes elementary reactions that are induced by radiation and, in pure monomers, can lead to chain-initiating free radicals and radical ions.

Figure 1 C shows how monomeric radicals can be produced from excited molecules M∗. The triplet states M∗(T), which after hydrogen abstraction can produce radicals of the $(MH)^\bullet$ type, are particularly important.

The majority of chain-initiating radicals and ions are produced some 10^{-8} to 10^{-6} s after the primary ionization event. Chain initiation is immediately preceded by elementary reactions such as energy, charge, and proton transfer, hydrogen abstraction, and recombination. In *liquids* these reactions are diffusion- controlled. The activation energy of the elementary reaction consists only of the diffusional part. Accordingly, almost no activation energy is required to initiate radiation-induced polymerization [32–36].

Because many of the transfer processes shown in Figure 1 C can occur at low temperature even in solids and liquids, and a diffusional approach of the reactants is not required, ionizing radiation is an ideal means of initiating polymerization. Other advantages of polymerization by irradiation of solids include

1) Generation of a homogeneous dose distribution
2) No contamination of the product by catalysts, photoinitiators, and the like
3) Only minimal temperature increases, since it is ionizing radiation that is absorbed
4) The oxygen sensitivity of the polymerization process is decreased

Figure 1. Radiation-induced reactions leading to the production of free radicals (radical ions) that initiate polymerization M = Monomer. M∗ = Excited molecular state of M (singlet, triplet). $RH^+ \ldots e_s^-$ = Ion pair.

1.1.2. Free-Radical Polymerization [32], [34], [37–42]

Free-radical addition polymerization, which is, for example, typical for many vinyl monomers, follows the mechanism of a classical chain reaction even when initiated by ionizing radiation. In many cases, the method of steady-state homogeneous kinetics can be applied to the description of radiation-induced polymerization. If all the elementary reactions that lead to the production of homogeneously distributed chain-initiating radicals $R^\bullet$ [= $(MH)^\bullet$ in Fig. 1] in irradiated monomers M are combined as $M \rightarrow 2\,R^\bullet$ with allowance made for chain propagation and termination, the following reaction scheme is obtained:

Initiation:

$$M \rightarrow 2\,R^\bullet \tag{1}$$

Initiation rate:

$$v_s = k_s\,[M]\,D^\bullet \tag{1a}$$

where v_s is the initiation rate, $D^\bullet$ the dose rate in Gy/s, and k_s [M] the production rate of $R^\bullet$ in mol L^{-1} Gy^{-1}.

Chain propagation:

$$R^\bullet + M \rightarrow RM^\bullet \tag{2a}$$

$$RM_n^\bullet + M \rightarrow RM_{n+1}^\bullet \tag{2b}$$

Rate of chain propagation v_p:

$$v_p = k_p\,[RM^\bullet]\,[M] \tag{2c}$$

Chain termination:

$$RM_n^\bullet + RM_m^\bullet \rightarrow P_{n+m} \tag{3a}$$

$$RM_n^\bullet + RM_m^\bullet \rightarrow P_n + P_m \tag{3b}$$

Rate of chain termination v_t:

$$v_t = k_t\,[RM^\bullet]^2 \tag{3c}$$

In the steady state,

$$v_s = v_t \tag{4a}$$

$$k_s\,[M]\,D^\bullet = k_t\,[RM^\bullet]^2 \tag{4b}$$

and the steady free-radical concentration is

$$[RM]^\bullet = \{(k_s/k_t)\,[M]\,D^\bullet\}^{1/2} \tag{5}$$

If the kinetic chain length is sufficiently large, the overall rate v of a chain reaction can be set equal to the propagation rate:

$$v = k_p\,[RM^\bullet]\,[M] \tag{6a}$$

$$v = k_p\left\{(k_s/k_t)^{1/2}\,D^{\bullet 1/2}\right\}[M]^{3/2} \tag{6b}$$

Table 1. G value for free-radical formation G (R) and activation energy E_a of radiation-induced polymerization for several monomers

Monomer	$G(R)$, molecules/100 eV	E_a, kJ/mol
Styrene	0.69	27.8
Methyl methacrylate	11.5	20.6
Vinyl acetate	12.0	23.9
Acrylonitrile	11.2	12.6 – 54.6
Methyl acrylate	≈15	≈21
Ethylene	4.4	

Given a fixed dose rate, the overall rate of radiation-induced free-radical polymerization depends on the rate constants of the propagation and termination reactions and, via the production rate of primary radicals $R^\bullet$, on their G value (Table 1). The overall polymerization rate (unit mol L^{-1} s^{-1}) is proportional to the square root of the dose rate, at least in the range of low dose rates (Fig. 2, region 1). This, however, applies only to monomers for which no part of the polymer precipitates during the reaction. Exceptions are ethylene, vinyl chloride, acrylic acid, and acrylonitrile. The kinetics of chain propagation and chain initiation are largely the same as those of the chemically-initiated chain reaction. The activation energies for radiation-induced polymerization (Table 1), are primarily the activation energies of the chain propagation step.

Figure 2. General dependence of polymerization rate v and mean degree of polymerization P_n on dose rate, according to [32]

As the dose rate increases (Fig. 2, region 2), chain termination by primary radicals becomes more important and effectively competes with reactions (3 a) and (3 b):

$$RM_n^\bullet + R^\bullet \rightarrow RM_n R \qquad (7)$$

If the dose rate is increased further (region 3), a state is reached in which all propagating chains are terminated by primary radicals. The molecular mass of the product polymers falls off sharply. The monomer consumption is no longer governed by chain propagation (v shown by dashed curve) but by the radiolysis of the monomer. In region 4, radiolysis of the monomer is the sole process. The degree of polymerization drops to 1.

This unfavorable dose-rate dependence, however, is not a limiting factor in the industrial use of high dose rates (such as those in electron irradiation) for polymerization processes. Two factors ameliorate the detrimental effect of high dose rates: If the polymer precipitates as it is produced, the kinetic relations stated above are no longer valid. The overall polymerization rate is described by dose-rate exponents between 0.5 and 1. In highly viscous media, chain termination is strongly hindered by the low diffusion coefficient, and here the dose-rate exponent can again reach a value of unity.

As is shown in more detail in Section 1.3, electron bombardment even at dose rates of 10^5–10^6 Gy/s is very effective in achieving free-radical polymerization or cross-linking of high-viscosity monomer–prepolymer mixtures such as those used industrially as binders for paints, printing inks, adhesives, etc.

Ionizing radiation can act on both monomer molecules and polymer macromolecules by direct electron mechanisms, producing excitation or ionization. The formation of polymeric free radicals $P^\bullet$ cannot be neglected at conversions as low as ca. 20 %. At high conversions, there are two competing initiation reactions:

$$M \rightsquigarrow 2R^\bullet \qquad (8a)$$

$$P \rightsquigarrow 2P^\bullet \quad \text{or} \quad P^\bullet + R^\bullet \qquad (8b)$$

As the monomer conversion increases, branched-chain polymers (homograft polymers) are obtained. When the monomer concentration has declined to the point that not all the free radicals produced can be scavanged by monomer molecules, radiolysis of the polymer becomes dominant, leading to either cross-linking or chain termination. Figure 3 shows schematically the phases of radical polymerization in a plot of conversion versus dose.

Figure 3. Processes in irradiated monomers versus dose, according to [40]

1.1.3. Ionic Polymerization [32], [34], [41], [43–45]

If monomers, such as those in Table 2, are purified of trace water and irradiated at sufficiently high dose rates, polymerization can be initiated by free ions that have escaped recombination with their partners in the primary ion pair (Fig. 1 C). Cationic polymerization is the principal type observed for the monomers of Table 2. Styrene and α-methylstyrene can, however, also be anionically polymerized. In radiation-induced ionic addition polymerization, chain propagation and chain termination exhibit kinetics similar to that in radical chain polymerization.

Table 2. Rate constants for the chain propagation reaction with superdry monomers, according to [40]

Monomer	t, °C	Rate constant, L mol^{-1} s^{-1}	Activation energy, kJ/mol
Styrene	15	3.5×10^6	0
α-Methylstyrene	0	4×10^6	0
	30	3×10^6	0
Cyclopentadiene	−78	6×10^8	<8
Isobutene	0	1.5×10^8	<8
Isobutyl vinyl ether	30	3×10^5	<21

$$\text{Initiation: } M \rightsquigarrow M^+(M^-) \quad (9)$$

$$\text{Propagation: } M^+ + M \longrightarrow MM^+ \quad (10a)$$

$$M_nM^+ + M \longrightarrow M_{n+1}M^+ \quad (10b)$$

In the presence of water, deprotonation of the radical cation is a competing process:

$$M_nM^+ + H_2O \longrightarrow M_n M^\bullet(-H^+) + H_3O^+ \quad (11)$$

Chain termination:

$$M_n M^+ + M_m M^- \longrightarrow P_1 \quad (12a)$$

$$M_n M^+ + Y^- \longrightarrow P_2 \quad (12b)$$

where Y^- denotes an impurity.

Similarly to radical chain polymerization, the overall rate of radiation-induced ionic polymerization is given by

$$v = k_p\,[M_n M^+]\,[M] \quad (13)$$

$$v = k_p\,(k_s/k_t)^{1/2}\,D^{\bullet 1/2}\,[M]^{3/2} \quad (14)$$

and the mean lifetime τ of charge carriers in the steady state by

$$\tau = \frac{[M_nM^+]}{k_s\,[M]\,D^\bullet} = (1/k_t \cdot k_s\,[M]\,D^\bullet)^{1/2} \quad (15)$$

The kinetic chain length $\hat{L}$ is

$$\hat{L} = k_p\,[M]\cdot\tau \quad (16)$$

The rate constants for chain propagation in radiation-induced ionic polymerization are much larger than those for conventional ionic polymerization, where the active species consist of thermodynamically stable ion pairs. Table 3 compares the propagation rate constants for the addition polymerization of styrene in various processes. Measurements of the molecular mass distribution of radiation-polymerized polystyrene have shown that free-radical and ionic polymerization can occur at the same time if traces of water are present in the monomers. If the dose rate is increased, for example if polymerization is initiated by fast electrons, the effect of impurities on cationic chain propagation can be minimized.

Table 3. Comparison of chain propagation rate constants k_p for addition polymerization of styrene, according to [45]

Initiation by	Solvent	t, °C	k_p, L mol^{-1} s^{-1}
Radiation, free cation	styrene	15	3.5×10^6
$Bu_4N^+CF_3SO_6^-$, free cation	dichloroethane	30	3.0×10^6
Free anion	tetrahydrofuran	25	6.0×10^4
Free radical	styrene	20	35
Cationic ion pair	sulfuric acid	25	7.7

Figure 4. Radical formation processes in irradiated polymers (schematic)

Other monomers that are polymerized by a free-radical process at low dose rates and a cationic process at higher dose rates include α-methylstyrene, isobutylvinyl ether, and isoprene. With butadiene only cationic polymerization is found.

1.1.4. Radiation-Induced Polymerization of Solid Monomers [44], [46–51]

Diffusion processes in the solid phase are orders of magnitude slower than in the liquid phase. Although radiation-induced polymerization of solid monomers is also initiated by free radicals or ions, the much slower diffusion results in some special features of solid-phase polymerization. Chain propagation may slow down, and chain termination by free-radical combination is also strongly hindered. The lifetime of free radicals in the solid phase may be eight to ten orders of magnitude longer than that in the liquid phase. The migration of free radicals in solid monomers and polymers is partly explained by nondiffusion processes such as the migration of radical sites due to a series of hydrogen addition and abstraction reactions.

Differences in polymerization kinetics are observed between crystalline and amorphous monomers. In some cases, the crystal structure of the monomer determines that of the polymer (e.g., 1,3,5-trioxane). Monomers that can be polymerized in the solid phase by ionizing radiation include acrylamide, diketene, trioxane, tetraoxane, pentoxane, styrene, and methacrylates.

In mixtures of monomers, for example acrylamide or acrylic acid with glass-forming matrices, radiation-induced polymerization has been observed to occur in the glassy state.

Methacrylates and acrylates in the glassy state can be polymerized especially well at low temperatures. Since scarcely any three-dimensional contraction occurs during this process, polymers with good optical properties are obtained in this way.

Bioactive substances such as enzymes can be readily introduced into glass-forming acrylate monomers, cooled, and immobilized through polymerization of the matrix. These biofunctional polymers are used in biomedical fields and biochemistry.

1.2. Action of Ionizing Radiation on Polymers – Polymer Modification

1.2.1. Reaction Mechanisms [52–63]

The action of ionizing radiation on polymers commonly results in simultaneous cross-linking and degradation reactions. These processes can be detected through the change in mean molecular mass of the polymers, the formation of low molecular mass reaction products such as H_2,

CH_4, CO, CO_2, hydrogen halides, and changes in the physical properties.

In addition, oxidation reactions occur in the presence of atmospheric oxygen. Even low doses of radiation can markedly change the physical properties of the polymer. Formally, free-radical formation processes can be accounted for by the cleavage of main-chain and side-chain bonds in the polymer (Fig. 4).

Figure 5. Radical formation processes in polyethylene irradiated at 120 °C, according to [61]

The free-radical formation mechanism in irradiated polymers is generally far more complex and cannot be satisfactorily explained by the assumption of direct bond cleavage. Attempts to use pulse radiolysis to explain free-radical formation in low density polyethylene (LDPE) heated to 120 °C have led to the (simplified) reaction scheme of Figure 5. The radiation-generated primary products in polyethylene (PE) are excited polymer units PE∗, "trapped" electrons e^-_{tr}, and cationic polymer units $PE^{\bullet+}$. Recombination of electrons and cations again leads to excited polymer units, which decompose into alkyl and hydrogen radicals. Alkyl radicals, however, can also be produced by deprotonation of radical cations $PE^{\bullet+}$. Elimination of H_2 competes with deprotonation. Products of H_2 elimination are olefinic cations; these, however, can also be produced by charge transfer to double bonds already present in PE. Electrons are probably stabilized on existing carbonyl groups to form anions. Recombination of these anions with cations leads to radiation-generated double bonds.

In the presence of oxygen, radiation-induced degradation is commonly greatly accelerated. The initiation step is the formation of peroxy radicals:

$$-C-C^{\bullet}-C- + O_2 \longrightarrow -C-\overset{\overset{\displaystyle OO^{\bullet}}{|}}{C}-C- \quad (17)$$

Hydroperoxides are obtained after hydrogen addition; these can decompose to alkoxy and OH radicals

$$-C-\overset{\overset{\displaystyle OOH}{|}}{C}-C \longrightarrow -C-\overset{\overset{\displaystyle O^{\bullet}}{|}}{C}-C- + OH^{\bullet} \quad (18)$$

or can form carbonyl groups:

$$-C-\overset{\overset{\displaystyle OOH}{|}}{C}-C \xrightarrow{+H} -C-\overset{\overset{\displaystyle O}{\|}}{C}-C- + H_2O \quad (19)$$

1.2.2. Cross-Linking and Degradation

When polymers are irradiated, cross-linking and degradation usually occur simultaneously. Cross-linking occurs when two species (e.g., free radicals) produced on neighboring polymer units recombine (Fig. 4). The relative molecular mass of the branched macromolecules produced increases with increasing dose and the melting point rises. At the same time, a temperature range is found in which the cross-linked polymer can possess rubber elasticity and is no longer completely soluble. The minimum dose necessary for gel formation (i.e., for production of cross-links) is called the *gel dose* D_{gel}. If two monomer units form a cross-link and no simultaneous chain degradation occurs, the gel dose (in rad) is given by

$$D_{gel} = \frac{100 \cdot N_A}{2 \cdot 6.24 \times 10^{13} \cdot G(X) \cdot M_r} \quad (20)$$

where $G(X)$ is the number of cross-links produced per 100 eV of absorbed energy, M_r is the number-average relative molecular mass of the uncross-linked polymers, and N_A is the Avogadro constant.

Thus the G value for cross-linking can be determined by measuring the gel dose. If *degradation* takes place at the same time, the gel dose increases; $2\,G(X)$ in Equation (20) is then replaced by $[2\,G(X) - G(S)/2]$, where $G(S)$ is the number of cleaved bonds in the main chain per 100 eV of absorbed energy.

The radiation-induced degradation of a polymer leads to a decrease in molecular mass. Gel formation is possible only if $G(S)/G(X) < 4$. For linear polymers, the degree of cross-linking is proportional to the dose. Its dependence on the dose rate, the chemical structure of the polymer, and the type of ionizing radiation is not significant. The G value for cross-linking is only partially influenced by the molecular mass of the polymer but it can be changed significantly by additives (sensitization or desensitization of cross-linking).

The extraction method is often used to determine the *cross-linking density* q. CHARLESBY and PINNER [64] found the following relation for the soluble (sol) content s,

$$s + \sqrt{s} = p/q + 1/qP_n \cdot D \tag{21}$$

where s is the sol content, q the cross-linking density, p the degradation density, P_n the number average degree of polymerization, and D is the dose.

If $s + \sqrt{s}$ is plotted versus $1/D$, the intersection of the resulting line with the vertical axis gives the ratio p/q of the degradation density to the cross-linking density.

The degree of cross-linking can be also determined by measurement of the swelling capacity and elastic modulus of the network. The measurement of spin – spin relaxation times (T_2) by pulsed NMR yields direct information about network formation in polymers and thus about the degree of cross-linking [65], [66]. Solid-state NMR studies can also supply information about cross-links and new terminal groups produced by irradiation.

The above model of a statistically distributed production of cross-links in polymers with statistically distributed molecular masses has to be modified if a crystalline phase and "chain folding" are present. For example, many experimental indications show that radiation-induced cross-linking in, for example, polyethylene occurs mainly in the amorphous phase [57]. Only at very high doses ($> 10^6$ Gy) can a marked decline in crystallinity be seen.

Vinyl polymers having a structure of the type with R^1 and R^2 = alkyl, COOR, OH, or halogens are predominantly degraded. When $R^1 = R^2 = H$, then cross-linking becomes dominant. Aromatic side groups transform much of the absorbed energy without any chemical consequences and thus provide stability against degradation. CO groups in the main chain, on the other hand, promote degradation. Polymers whose monomers exhibit a high enthalpy of polymerization are, as a rule, predominantly cross-linked; polymers that readily form monomers by pyrolysis have a tendency to degrade.

The following are mainly *cross-linked*: polyethylene, polypropylene, polystyrene, poly(vinyl chloride), poly(vinyl alcohol), polyacrylates, polyesters, polyamides, polysiloxanes, natural rubber, synthetic rubber (except butyl rubber), phenol – formaldehyde resins, aminoformaldehyde resins, and polysiloxanes.

The following are mainly *degraded*: polyisobutylene, butyl rubber, poly-α-methylstyrene, poly(vinylidene chloride), polymethacrylates, polymethacrylamides, polytetrafluoroethylene, cellulose and its derivatives, polytrifluoroethylene, and polycarbonates.

1.2.3. Graft Copolymerization [32], [34], [67], [69–78]

The reactive species produced when ionizing radiation acts on polymers or monomers are primarily free radicals and, in a few cases, radical ions. Radiation graft copolymerization offers the following general advantages:

1) Good range of variation for the initiation step
2) Initiation under conditions where conventional methods fail (low temperature, solid-phase polymerization)
3) Freedom from chemical initiators or catalysts ("clean" systems)

However, special conditions must be applied to every system to be grafted, on account of dif-

ferences in the formation mechanisms of reactive species, the *G* values, and the reactivity.

The only process that has gained practical importance is *heterogeneous grafting*. Here the polymer to be activated is in, for example, solid form while the monomer can be in the vapor or liquid state (see Table 8).

The following methods are available for graft copolymerization:

Preirradiation Method. The polymer P_A is irradiated with oxygen exclusion. The free radicals formed are long-lived and react with the monomer M_B to form a side chain:

$$P_A \rightsquigarrow P_A^\bullet + H^\bullet \quad (22\,a)$$
$$H^\bullet + P_A \longrightarrow P_A^\bullet + H_2 \quad (22\,b)$$
$$P_A^\bullet + n\,M_B \longrightarrow P_A\,n\,M_B \quad (22\,c)$$

Preirradiation is well suited to continuous grafting processes, such as the electron irradiation of polyethylene film followed by grafting of acrylic acid.

Peroxide Method. When the polymer P_A is irradiated in air, the active centers formed are chiefly hydroperoxides. These, after heating or UV irradiation if necessary, decompose to give oxygen and OH radicals.

$$P_A \xrightarrow{O_2} P_A O_2^\bullet \xrightarrow{+H} P_A OOH$$
$$\xrightarrow{\Delta,\,UV} P_A O^\bullet + OH^\bullet \quad (23\,a)$$
$$P_A O^\bullet + M_B \longrightarrow P_A OM_B \text{ (graft copolymer)} \quad (23\,b)$$
$$OH^\bullet + n\,M_B \longrightarrow n\,M_B^\bullet OH \text{ (homopolymer)} \quad (23\,c)$$

Homopolymerization can be lowered by the addition of OH scavengers (Fe^{2+}).

Simultaneous Method. The polymer P_A and the monomer (vapor, liquid, or solution) in contact with it are simultaneously irradiated.

$$P_A \xrightarrow{O_2} P_A^\bullet, \quad M_B \xrightarrow{O_2} M_B^\bullet \quad (24\,a)$$
$$P_A^\bullet + M_B \longrightarrow P_A M_B \text{ (graft copolymer)} \quad (24\,b)$$
$$M_B^\bullet + n\,M_B \longrightarrow M_B\,n\,M_B \text{ (homopolymer)} \quad (24\,c)$$

This method is very efficient because of low radical losses (e.g., polyethylene – styrene), but it also yields considerable amounts of homopolymer.

In many cases, radiation-induced graft polymerization is sensitized by additives (polyfunctional monomers, acids, inorganic salts).

1.3. Applications

1.3.1. Electron-Beam Curing of Paints, Printing Inks, Adhesives, and Release Agents (see also → Paints and Coatings, Chap. 3.7.; → Printing Inks, Chap. 10.1.)

1.3.1.1. Principle of Radiation Curing [69], [79–91]

As proposed by the RadTech Conference 1988, radiation curing is defined as "The use of electron beam or ultraviolet radiation as an energy source to induce the rapid conversion of especially formulated 100 % reactive liquids to solids."

The polymerization and cross-linking of predominantly solvent-free coatings and printing inks can be initiated either by ionizing radiation (in industry, mainly fast electrons with energies between 120 and 300 keV) or by UV quanta.

Initiation by *electrons* leads to the primary free-radical polymerization and cross-linking processes described in Section 1.1. Cationic polymerization is only found in rare cases. With *UV excitation*, the radiation quanta are first absorbed by photoinitiators. After excitation, the photoinitiators form active species (free radicals or protons), which initiate the chain reaction of radical or cationic polymerization. In industry, these two types of radiation curing are in competition with thermal curing. The radiation process offers significant advantages over the thermal process:

1) No solvent release
2) Reduction of energy consumption by as much as an order of magnitude
3) Significantly smaller space requirement
4) High production rates
5) Elimination of processing steps; possibility of continuous coating and curing (since the cured products can be stored or forwarded to downstream operations immediately)
6) Generally high quality of coating or printing

Figure 6. Depth – dose distribution (relative dose versus mass per unit area) for ISO – 280 eV electrons [110]

7) Only slight increase of temperature in curing, which makes it possible to process temperature-sensitive substrates

Electron-beam curing processes have the drawback that raw materials for radiation-cured coatings and inks are more expensive than conventional ones and some contain skin-irritating ingredients. Energetic and promising work is under way to remedy these defects through the development of low- cost feedstocks and formulations with improved service properties [84–90].

The discussion that follows will deal chiefly with the electron-beam curing of solvent-free coatings. The dose distribution in the coating and substrate is particularly important for the curing process.

Typical formulation for electron-beam curing require doses between 10 and 50 kGy. Given the mass per unit area M_A of coating plus substrate, the required electron energy and the overdose (dose inhomogeneity) are determined from the depth – dose distribution (Fig. 6) because the following relation holds:

$$M_A = \frac{m}{A}$$

$$\frac{M_A}{\varrho} = \frac{m}{A} \cdot \frac{A \cdot d}{m} = d$$

where d is the penetration depth. Low-energy electron accelerators suitable for industrial electron-beam curing are on the market, together with raw materials for radiation- curing formulations.

1.3.1.2. Chemistry of Electron-Beam Curing [79], [80], [91–96]

Coatings for electron-beam curing generally consist of the following:

1) Prepolymers, usually with acrylic ($H_2C{=}CH{-}CO{-}O{-}$) double bonds or double bonds in the main chain (polymaleates and polyfumarates)
2) Monomers, usually acrylates, used as reactive thinners to reduce the viscosity and influence the properties of the coating
3) Pigments and dyes; if needed, fillers, flatting agents, and additives to improve the film and surface properties

Acrylated Prepolymers. Many highly reactive prepolymers can be produced by acrylation of oligomers (e.g., epoxy resins, urethanes, polyesters, polyethers, silicones, oligobutadiene, melamine derivatives, cellulose, and starche) with a variety of agents (e.g., acrylic acid, acrylamide, hydroxyethyl acrylate, and glycidyl acrylate). Prepolymers are the principal ingredients of coating formulations and largely determine the basic properties of the coating.

Polyester acrylates, epoxy acrylates, polyurethane acrylates, and silicone acrylates have found wide use in industry (see Fig. 7).

Figure 7. Acrylated prepolymers for radiation-curable binders

Polyester acrylates, even those with molecular masses of 300 – 1000, have low viscosities. They are suitable for coatings with good elasticity and high pigment content.

Epoxy acrylates are produced from bisphenol A, aliphatic and cycloaliphatic expoxides, epoxidated fatty acids (e.g., soybean oil), and novolacs. *Aromatic epoxy acrylates* enable the production of radiation-cured printing inks and coatings for wood and paper. They have a high viscosity and, in combination with suitable monomers, yield hard, scratch-resistant coatings. *Epoxidated and acrylated oils* generally have low viscosities and good cross-linking properties; they are not irritating to the skin but are less reactive. Good thermal and chemical stability is achieved with *acrylated novolacs.*

Urethane acrylates, in general, are highly reactive and are applied in high-gloss coatings with good chemical and scratch resistance. They show good adhesion to a variety of substrates. The hardness and flexibility of the films can be controlled through, for example, the chain length of the oligomer.

Silicone acrylates are chiefly employed for the production of antiadhesive papers, separating foils, and adhesive tape backings, and also for the coating of glass fibers.

Polydimethylsilanes are usually modified with vinyl, acrylate, or thiol groups to lend them adequate reactivity.

Monomers. Acrylate esters have found aceptance in radiation-curing practice because of the range of different products on the market as well as their availability, reactivity, viscosity, and price. The monomers, also called reactive thinners, form a high-molecular-mass network with the oligomer after curing. In order to attain an adequate degree of cross-linking, principally bifunctional and polyfunctional acrylates are employed. Monofunctional acrylates give a less reactive coating; they are not suitable constituents for industrial formulations because of their volatility, odor, and skin-irritating action.

In what follows some bifunctional and polyfunctional acrylates are listed that have found

Table 4. Low-energy electron accelerators used in industry

Manufacturer, model	Cathode configuration	Electron energy, keV	Beam power, kW	Maximum beam width, m	Remarks
Energy Sciences, Inc. (ESI), US, Electrocurtain	linear cathode with control grid	150 – 300		2.3	up to 4 cathode systems in one accelerator head
Electrocure [98–101], [103]	multicathode		200		used in printing industry
Radiation Polymer Co. (RPC), US [104–106]	multicathode with 2 grids	150 – 300	200	2.3	
Broad Beam Dual Accelerator	multicathode	300	980	2.3	consists of 2 accelerators
Polymer Physik (PP), Germany. Scanner [108–111]	needle cathode	150 – 280	100	2.0	2 cathode systems possible
LEA [112]	linear cathode with no control grid	120 – 200	60	1.0	used chiefly in printing industry
Nissin-High Voltage Co. (NHV), Japan	linear cathode	150 – 200	200	1.0	
Scanner [107]	needle cathode	300 – 500	65	1.2	

broad use in industrial coatings and printing inks (abbreviations are given in parentheses):

Tripropylene glycol diacrylate	(TPGDA)
1,6-Hexanediol diacrylate	(HDDA)
Dipropylene glycol diacrylate	(DPGDA)
Trimethylolpropane triacrylate	(TMPTA)
Trimethylolpropane ethoxytriacrylate	(TMP(EO)TA)
Trimethylpropane propoxytriacrylate	(TMP(PO)TA)
Pentaerythritol triacrylate	(PETA)
Glyceryl propoxytriacrylate	(GPTA)

Ethoxylation and propoxylation of acrylates have been used to produce monomers which are less skin-irritant but highly reactive. Well-cured coatings contain an extremely low amount of extractable residual monomers or other products that tend to migrate.

Use of Inert Atmospheres. Free-radical polymerization and cross-linking processes are inhibited by oxygen. Oxygen reacts both with the initiating free radicals and with the propagating free-radical chain. The reaction with oxygen either prevents chain propagation or terminates the propagating chain. The coating surfaces remain tacky ("oxygen-inhibited") and exhibit totally inadequate properties. Accordingly, the residual oxygen concentration in the irradiation zone must be lowered to 100 – 1000 ppm (depending on the coating system) by inert-gas purging. At present, virtually the only inert gas used is nitrogen, which is obtained by vaporizing liquid nitrogen (purity $> 99.99\,\%$).

In the electron-beam curing of, e.g., coatings on flexible substrates, the engineering requirement of inert conditions with minimum nitrogen consumption is met by using a directed high-velocity jet of inert gas to "peel off" the air layer on the coating at the inlet to the curing zone. The irradiation chamber is then purged in such a way as to maintain the most laminar flow conditions possible. The inert-gas consumption can thus be reduced to 70 – 100 m^3/h (STP) for a curing zone 1 m wide and a product speed of 300 m/min.

Often, part of the nitrogen required for inertizing is used for convective cooling of the accelerator beam window. The inert gas also prevents the formation of ozone, which cannot be prevented when air is irradiated.

1.3.1.3. Industrial Irradiation Equipment, Low-Energy Electron Accelerators [69], [78], [81–83], [97–112]

Accelerators generating electrons with energies between 120 and 300 keV are employed for the electron-beam curing of coatings and printing inks or rigid and flexible substrates. This energy range is sufficient to cure coatings with mass per unit area between 60 g/m^2 (120 keV) and 400 g/m^2 (300 keV), given a 20 % dose inhomogeneity in the coating (Fig. 6) and it permits the use of simple accelerators with integral radiation shielding. Low-energy accelerators are a mature technology. Under industrial conditions, they can be used as computer-controlled subsystems in coating machines, printing presses, and laminating machines, etc. Their operating

parameters (electron energy, beam power, width of irradiation zone, homogeneity of dose over the irradiation width) can be precisely matched to the results of the industrial process in which the accelerators are used.

At present, the electron-beam power is limited to around 200 kW, the irradiation width to 2.5 m, and the product speed to some 1500 m/min (for an applied radiation dose of 10 kGy). In graft copolymerization applications, however, a dual accelerator with a 2.3 m irradiation zone width, 300 keV energy, and 980 kW beam power is being built [106]. The estimated number of low-energy electron accelerators in industrial plants in 1992 is ca. 150 units worldwide.

Table 4 gives the parameters and manufactureres of the most widely used modern low-energy accelerators. In all the accelerator types shown in Table 4 the electrons are produced by a hot cathode held at a high voltage. As they travel across the potential difference between cathode and anode (the outer wall of the accelerator beam window), the electrons acquire the energy needed to pass through the titanium foil window. The energy loss of 120 keV electrons in a 15 µm titanium foil is as much as 30 %. This fact sets a practical lower limit on the electron energy. An upper limit on the electron-beam power is given by the maximum possible current per square centimeter of window area which is 0.2 mA/cm^2.

The accelerating voltage limit of 300 keV is dictated, firstly, by the physical capabilities of electron acceleration in a simple cathode – anode system with no intermediate

Figure 9. Applications of electron-beam curing versus electron energy and electron current per cm of window length

electrodes and, secondly, by the fact that the lead shielding for higher voltages is not easy to handle and offers little advantage over fixed concrete shielding.

If a point (needle) cathode is used, the roughly pencil-sized electron beam must be deflected by a varying electromagnetic field so as to cover the required irradiation zone. This beam deflection or scanning gives the name scanner to this type of accelerator (Fig. 8 A). Alternatively, a hot wire of appropriate length can also be chosen as the electron emitter; the electrons are then focused by electron optics and accelerated toward the beam window. Systems of this type are shwon in Figure 8 B – D. Several configurations are distinguished: linear cathode with con-trol grid (Electrocurtain, Fig. 8 C), linear cathode without control grid (LEA, Fig. 8 B), and multicathode arrangements with the hot wires transverse to the long axis of the window ("Broad Beam," Fig. 8 D).

Linear-cathode and multicathode accelerators are more compact than scanners, but do not offer such good dose homogeneity over the irradiation zone width.

1.3.1.4. Industrial Applications of Electron-Beam Curing [69–79], [81–90], [102], [113–123]

There are presently three major applications for electron-beam curing: upgrading the surfaces of rigid and flexible materials, and printing. These fields impose different requirements on electron accelerators (Fig. 9). The electron-beam curing of coatings on *rigid substrates* – chiefly furniture, doors, laminated panels, and ledges – requires relatively high electron energies. Some of these coatings have mass per unit area of 200 g/cm^2. When edges and small-area parts cannot be reached by direct electron irradiation, curing is effected by electrons scattered in the air.

Production rates in, for example, the furniture industry are not determined by the curing step but by other operations, such as feeding, discharge, and polishing, etc. Low to moderate beam powers are therefore adequate.

Electron-beam curing of coatings on *flexible* materials often takes place as the substrate passes from roll to roll. Production rates between 100 and 300 m/min are common, at coating weights of 1 – 30 g/m^2. Therefore, low electron

energies and moderate to high beam powers are needed.

In *printing*, especially in roll-fed offset printing, press speeds range from 600–1000 m/min, but printing speeds are somewhat lower. Despite the relatively low curing doses required for printing inks (15–25 kGy), extremely high beam powers with the lowest possible electron energies are required.

Table 5 summarizes important industrial applications of electron-beam curing.

1.3.2. Radiation-Induced Cross-Linking [69], [81–83], [124–137]

The radiation-induced cross-linking of polymers is an established industrial technology, especially in the following areas:

1) Cross-linking of cable insulation, tubes and pipes, and moldings
2) Heat-shrink materials
3) Vulcanization of elastomers
4) Processing of foamed plastics

Radiation-cross-linked products produced in the United States alone had a value of $\$ 1840 \times 10^6$ in 1988.

Industrial irradiation equipment comprises chiefly electron accelerators whose energy, beam power, and irradiation zone width can be opimally matched to the process requirements [138–147]. Only in a few exceptional cases (shrink-wrap films, thin elastomer coatings) can low-energy accelerators be employed. Because of the required electron penetration, accelerators with energies of 0.5–5 MeV and power < 200 kW are mainly used.

Radiation-induced cross-linking is competitive with peroxide cross-linking (initiated by thermal cleavage of peroxides) in the cable insulation sector. Although there is no fundamental difference in the chemistry of peroxide and radiation-induced cross-linking, aside from the initiation process, there are a number of process differences (Table 6).

1.3.2.1. Cross-Linking of Cable and Wire Insulation

The use of electron beams to cross-link cable and wire insulation is an economical and highly productive process. Insulation with a high heat resistance, which is thus stable against Ohmic heating and soldering operations (< 250 °C for brief periods), is easy to produce in this way. In addition to stability at high temperature, the solvent resistance and the mechanical properties of the insulation can be improved by cross-linking. Besides polyethylene, other radiation-cross-linkable polymers are increasingly used for wire insulation. Table 7 lists cross-linkable materials suitable for electrical insulation.

Table 7. Radiation-cross-linked materials for cable and wire insulation [124]

Material	Cross-linking dose, kGy
Polyethylene	200–300
Polyethylene (sensitized)	100–150
EPDM [a]	100–150
PVC (sensitized)	50–80
Sulfonated polyethylene	100–150
Polyvinylidene fluoride	80–160
EPR [b]	50–150
Ethylene–tetrafluoroethylene copolymer	60–100
Silicone rubber	200

[a] Terpolymer of ethylene, propene, and a diene.
[b] Ethylene–propylene rubber.

Thermoplastics and elastomers to be cross-linked often contain additives to either lower the cross-linking dose or to make cross-linking possible at all (PVC). Such additives can be polyfunctional unsaturated compounds, e.g., acrylates, methacrylates, vinyl, allyl, and acetylene compounds, or oligobutadiene, but inorganic, metallic, and organometallic compounds can also be employed.

In the radiation cross-linking of polyethylene insulation layers more than 10 mm thick, the accumulation of charge carriers leads to electrical breakthrough and damage to the insulation layer. Radiation- cross-linked insulation can therefore be used only for low-voltage and medium-voltage cables.

1.3.2.2. Vulcanization of Elastomers

Radiation-cross-linked elastomers (Table 7) are used chiefly for cable and wire insulation and in tire manufacturing [148], [149]. Cross-linking and degradation are again the main processes when elastomers are treated with radiation;

Table 5. Industrial applications of electron-beam curing

Surface treated	Application	Location
Solid materials		
Wood	door finishes	Europe
	finishes on front panels of furniture	Europe, USA
	lamination and lacquer finishes	USA
	coating of wood–cement panels	Europe
	edge curing	Europe
	coating of moldings (on all sides)	Europe
	coating of medium density fiberboard (MDF) panels	Europe
Gypsum	coating of gypsum panels	Japan
Metal	coating of metal panels	Japan
	coating of metal strip (roll-to-roll)	Japan
Flexible materials		
Paper	coating of paper used to decorate wood	Europe, USA, Australia
	silicone coating of paper for labels, protective films, dividers,	Europe, USA, Japan
	high-gloss lacquer coating of gift wrapping papers, etc.	USA, Europe, Australia
	metallizing of paper, coating with base lacquer, or transfer metallizing	Europe, USA
Films	cross-linking of pressuresensitive adhesives	Europe, Japan, USA
	production of films from liquid phase	Europe
	antistatic coatings	USA
	cross-linking of flock adhesives	USA
	antiscratch coating of, e.g., telephone cards	Europe
	magnetic coating on diskettes and video tape	USA, Japan
	lamination of films on plastic, etc.	USA
Printing media

	recoating in high-speed gravure printing	USA
	steel engraving	USA

Table 6. Comparison of peroxide and radiation-induced cross-linking

Property	Peroxide cross-linking	Radiation-induced cross-linking
Process temperature	high temperature (polymer melt)	normal temperature; only slight temperature raise by absorption of radiation
Energy consumption, ratio peroxide – radiation	5	1
Cross-linking rate	depends on peroxide concentration	depends on dose rate
Production costs, ratio peroxide – radiation	2.0 – 2.5	1 (1.5 – 2 $/kg)
Range	limited to polymers that can be extruded up to 250 °C	nearly universal
Crystallinity of polymer	diminished	unaffected
Gel content of cross-linked polymer	virtually always > 70 %, little possibility of variation	controllable through radiation dose

which process is dominant will depend on the elastomer, its composition, the type and quantity of additives, and the radiation dose. The required cross-linking dose is a function of the elastomer and the additives. The changes in elastomer properties due to vulcanization by heat treatment and radiation cross-linking are often very similar. Irradiation, however, permits homogeneous cross-linking in a simple way. More intense cross-linking at the surface, which can occur in heat treatment because of poor thermal conductivity of the elastomer, is not a problem with radiation cross-linking if sufficiently high electron energies are employed.

The possibility of using radiation cross-linking for parts of articles, as in tire manufacturing, leads to technological advantages in the production process, and savings of materials. Natural rubber can be replaced by synthetic material with no loss of quality. In addition, rates for production of, e.g., calendered rubber film are an order of magnitude higher than those in thermal vulcanization.

Figure 10. Radiation-cross-linked polyethylene foam; principle of PE expansion, according to [151]
a) PE before cross-linking; b) Cross-linked PE; c) Optimal viscosity; d) Decay of blowing agent; e) Melting point

1.3.2.3. Radiation-Cross-Linked Foam Polyethylene [150], [151] (see also → Foamed Plastics)

More than half of foamed polyethylene is produced with the aid of electron beams for cross-linking. Four processes are available for radiation cross-linking that have been developed by the following companies: Sekisui Chemical, Japan; Toray Industries, Japan; BASF, Germany; and Expanded Rubber and Plastics, United Kingdom.

In the United States, *slightly expanded* polyethylene foam (two-fold expansion) has been used in cable insulation. The compounds are foamed right on the wire and then cross-linked by radiation (Rayfoam L, Cheminax, by Raychem Corp.).

The foaming of polyethylene into a *highly expanded product* has proved difficult for a long time especially as the viscosity of polyethylene drastically decreases above its melting point. The melt viscosity of polyethylene drops abruptly above the metling point T_m, while that of cross-linked polyethylene declines gradually between T_1 and T_2 (Fig. 10). In the cross-linked state, polyethylene can be expanded in the much broader temperature range from T_1 to T_2. The expandability of cross-linked polyethylene at elevated temperature is a function of the dose. At 70 – 130 °C optimal percent expansion is obtained in the range of ca. 50 – 80 kGy. The expansion ratio of polyethylene is highest (15 – 20) for a gel fraction of 20 – 40 %. The expandability (foamability) of polyethylene bubbles also depends on the degree of cross-linking. Good foams are obtained after a cross-linking dose between 30 and 60 kGy when the pressure in the foam bubble is ca. 50 g/cm^2. The size of the individual polyethylene foam cell also depends on the gel fraction. Azodicarbonamide has proven suitable as a blowing agent.

1.3.2.4. Shrink Materials [152–154]

Polyethylene can easily be cross-linked into a product that will become rubber-elastic when heated. The structure of normally entangled polyethylene molecules includes crystalline and amorphous regions. Above the melting point of polyethylene, the crystalline regions vanish. Cross-linking (probably of the amorphous regions) results in the formation of a three-dimensional network. If the cross-linked polyethylene is heated above the melting point, it becomes rubber-elastic and can be mechanically deformed; if it is cooled in the deformed state to a temperature below the melting point, the crystalline portions form again and the material retains its deformation (frozen-in state). If the polyethylene is again heated above the melting point, it recovers from the deformation, taking on its original form (memory effect), i.e., it shrinks when it had previously been expanded.

Production of Shrink Tubes. First a tubular film is made with an extruder or the shaped part is fabricated with suitable pressing dies. The mold is then homogeneously irradiated with electrons (1.0 – 2.0 MeV for polyethylene tubing, 0.5 – 1.0 MeV for polyethylene films or web material) at a dose of 200 – 300 kGy. Excessive doses should not be applied the material properties so as to avoid deterioration of, e.g., poorer aging resistance. The tube is then expanded with heating and subsequently cooled.

1.3.3. Industrial Application of Radiation-Induced Graft Copolymerization [69], [81–83], [155–162]

Radiation-induced grafting is taking up a prominent role in industrial applications. Although large-scale applications are rare, a number of

special processes has been developed, most of them using electron irradiation to initiate grafting. High dose rates, controllable electron penetration depth, and the possibility of initiating the graft reaction at room temperature and atmospheric pressure are advantages of the electron-beam process. In most cases, the preirradiation or simultaneous method is employed. The flowsheet of a tpyical grafting apparatus for flexible polymers is shown in Figure 11. Properties that can be improved through grafting of polymer surfaces include: wettability, adhesion, printability, surface conductivity, biocompatibility, flammability, water absorption, resistance to certain chemicals, thermal stability, mechanical properties, chemical compatibility, hydrophilic and hydrophobic qualities. Table 8 lists some important applications.

2. Irradiation of Foods and Feeds

2.1. Introduction

Many of the traditional food-processing methods employ energy in one form or another. Examples are the use of conventionally generated heat, microwaves, or high-frequency electromagnetic waves in pasteurization and sterilization, and the use of solar radiation in drying. The irradiation of *foods*, utilizes the energy of ionizing radiation. Gamma rays, X-rays, and electron beams are all in practical service or under discussion at present. The Codex General Standard for Irradiated Foods, which has found wide international acceptance, states [163]:
"The following types of ionizing radiation may be used:

a) Gamma rays from the radionuclides ^{60}Co or ^{137}Cs;
b) X-rays generated from machine sources operated at or below an energy level of 5 MeV;
c) Electrons generated from machine sources operated at or below an energy level of 10 MeV."

The standard further provides that: "The overall average dose absorbed by a food subjected to radiation processing should not exceed 10 kGy."

The irradiation of *feeds* is carried out with the same radiation sources, except that doses higher than 10 kGy are permitted.

The list of references includes a selection of monographs [164–174].

2.2. Capabilities of Food and Feed Irradiation

The irradiation of foods and feeds can be practiced

1) To prolong shelf life
2) As a quarantine measure
3) To control pathogenic microorganisms and pathogenic parasites

Table 9 lists a number of important applications along with the radiation doses involved. The use of radiation doses higher than 10 kGy with foods is restricted to just a few cases, such as the irradiation of hospital meals for patients with immune system impairments and the irradiation of spices and dried vegetables up to maximum doses of 30 kGy, which is allowed in the United States.

The radiation treatment causes only a slight temperature rise in the treated product, so this method can be used to kill microorganisms even in frozen foods. In addition, an effective radiation dose can be administered through most packaging materials, so that the risk of recontamination after irradiation is virtually eliminated.

2.2.1. Prolongation of Shelf Life

While extending the shelf life of foods may not appear to be an urgent problem in the industrialized countries, the situation is more dramatic

Table 8. Radiation-induced graft copolymerization of selected polymer–monomer systems

Polymer	Monomer	Properties modified
Polyethylene	acrylic acid	hydrophilicity, wettability, antistatic property
	acrylamide	adhesion, permeability, permselectivity
	styrene	mechanical properties
	acrylates, methacrylates	surface structure, functionalization
Poly(vinyl chloride)	acrylic acid, methacrylic acid, polyfunctional methacrylates	adhesion, abrasion resistance
	styrene	impact strength
	acrylonitrile	thermal stability
Poly(ethylene terephthalate)	acrylic acid	hydrophilicity, surface structure
	acrylamide	biocompatibility
	poly(ethylene glycol) acrylate	antistatic properties
Polyamide	acrylic acid	hydrophilicity, antistatic properties
	acrylonitrile, vinyl acetate, methacrylate	processability (textiles), water vapor permeability
	hydroxyethyl methacrylate (HEMA)	functionalization, biocompatibility
Polyacrylonitrile	acrylic acid	moisture absorption, antistatic properties
Polypropylene	styrene, acrylic acid, methacrylates	functionalization, ion exchange
Cellulose	styrene, acrylic acid, HEMA	functionalization
Polyurethanes	*N*-vinyl-2-pyrrolidone, HEMA, acrylamide	biocompatibility
Fluoropolymers	styrene, *N*,*N*-diethylacrylamide	functionalization, hemocompatibility
	N-vinylpyrrolidone	membranes

Table 9. Purposes of food irradiation according to [169]

Food	Main objective	Means of attaining objective	Dose, kGy
Low-dose treatments (up to about 1 kGy)			
Potatoes, yam tubers, onions, garlic, ginger, chestnuts	extension of storage life	control of sprouting and germination	0.05 – 0.15
Certain fruits and vegetables	improved keeping properties	delay in ripening and ageing	0.25 – 1
Cereal grain, flour, dried fruits and vegetables, nuts, pulses	prevention of losses caused by insects	killing or sexual sterilization of insects	0.2 – 0.7
Fruits	prevention of spreading of pests; quarantine treatment	killing or sexual sterilization of insects	0.2 – 0.7
Pork, beef, fish	prevention of parasitic disease transmitted through food	destruction of parasites (e.g., *Trichinella spiralis*)	0.3 – 0.5
Medium-dose treatments (about 1 – 10 kGy)			
Certain fruits and vegetables, sliced bread	improved keeping properties	reduction of bacteria, molds, and yeasts	1 – 3
Meat, poultry, fish	improved refrigerated storage	reduction of certain microorganisms (growing at refrigeration temperatures)	1 – 5
Meat, poultry, eggs, egg powder, froglegs, frozen seafood, and other foods	prevention of foodborne diseases	destruction of *Salmonella shigella*, *Campylobacter*, *Vibrio*, *Yersinia*, and other nonspore-forming pathogens	3 – 10
Spices, dried vegetables, and other food ingredients	prevention of contamination of food due to the ingredients	reduction of microorganisms in the ingredients	3 – 10
High-dose treatments (about 10 – 45 kGy)			
Meat, poultry	long-term storage without refrigeration	destruction of spoilage organisms and pathogens, including spore-formers	25 – 45
Hospital meals	to supply patients with sterile meals	destruction of spoilage organisms and pathogens, including spore-formers	25 – 45

in some of the developing countries. For example, one African study estimated that losses of foods amounted to more than 35×10^6 t in Africa during the year 1980 [175]. Approximately 1 t of food will nourish one person for one year; hence losses in Africa represent the food needed by at least 35×10^6 persons a year.

According to WHO research, the estimated loss of grains and legumes from storage in the developing countries is at least 10 %. In the case of noncereal products, vegetables, and fruits,

the losses due to microbial contamination and spoilage are estimated at up to 50 %. Products such as dried fish are reported to be subject to 25 % losses due to insect infestation, with an additional 10 % loss by spoilage.

Inhibition of Germination and Sprouting. Treatment with a low radiation dose prevents the germination and sprouting of many products, such as potatoes, yams, onions, garlic, ginger, and chestnuts. Irradiation also prevents germination of barley during malting, with a significant economic benefit; in contrast, very low doses of radiation stimulate the germination of barley.

Disinfestation. Irradiation at a relatively low dose kills or sterilizes all developmental stages of the common organisms that infest grains, including eggs laid in the grain. Dried fruits, vegetables, nuts, and dried fish can also be protected from insect losses by irradiation, even after packaging.

Prolongation of Shelf Life of Easily Spoiled Foods. The shelf life of many fruits and vegetables, as well as those of meat, poultry, fish, and other seafood, can be substantially extended – if not doubled – through irradiation alone, or through a combination of cooling with doses of radiation low enough to leave the flavor and other qualities of the product unchanged. In the case of fruits that are sensitive to high radiation doses (e.g., mangoes), a combination of gentle heat treatment (dipping in hot water) and low-dose irradiation is successfully employed.

Retardation of Ripening and Aging of Fruits and Vegetables. Low radiation doses retard the ripening process and/or the ageing of some fruits and vegetables, thus extending their shelf life. This technology can be used for instance, with mangoes, bananas, mushrooms, and asparagus.

Killing of Parasites. Examples of pathogenic parasites that are inactivated by irradiation are the nematode *Trichinella spiralis*, which occurs in pork and causes trichinosis, the beef and pork tapeworms, the protozoa in pork that cause toxoplasmosis, and various worms that can infest fish. All these organisms can be rendered harmless with relatively low doses of radiation.

2.2.2. Quarantine Measures

Food irradiation may heavily increase the growing trade in tropical and subtropical fruits, such as citrus, mangoes, and papayas. Because irradiation prevents the introduction of harmful insects without leaving residues in the fruits, this treatment offers an alternative to fumigation as a way of complying with quarantine regulations in many countries. Irradiation can even destroy flies and weevils that live in mango stones.

2.2.3. Control of Pathogenic Organisms

According to WHO research, diseases caused by foods represent one of the most widespread threats to human health and a significant constraint on economic productivity. The principal sources of such diseases are foods of animal origin, a high percentage of which are contaminated by pathogenic bacteria. Meat and meat products are the main cause of infections with trichinosis and toxoplasmosis. According to WHO estimates more than 10^9 cases of acute diarrhea occur annually in children younger than five years in the developing countries. Some 5×10^6 children die of this disease, which is largely caused by contaminated foods and contaminated water. This is not solely a problem of the developing countries but also affects the industrialized countries, as shown by the increase of Salmonella-caused infectious enteritis in the Federal Republic of Germany from about 30 500 reported cases in 1985 to about 114 500 in 1991.

Most pathogenic microorganisms and virtually all pathogenic parasites can be eliminated by irradiation. For example, only relatively low radiation doses are required to destroy the nonspore-forming bacteria *Salmonella*, *Campylobacter*, *Listeria*, and *Yersinia*.

A problem may, however, be posed by microorganisms that survive a treatment with a relatively low radiation dose, for example the spores of *Clostridium* and *Bacillus* species. There is a danger that certain applications of food irradiation will suppress spoilage- causing microorganisms to the extent that the extra shelf life of the treated food will allow a species such

as *Clostridium botulinum* to produce a dangerous toxin level. This threat can be averted only through special precautions such as cold storage.

2.3. History

The bactericidal action of ionizing radiation was described around 1900, giving rise to the notion of using such radiation for preservation purposes. The first patent on food irradiation was published in 1905 (British Patent 1609). This patent stated how the quality and shelf life of foods could be improved through the application of ionizing radiation. Concerned chiefly with cereals, the patent stressed that one advantage of using ionizing radiation lies in the replacement of the corresponding chemical treatments. The use of ionizing rays to control trichinae in pork was first discussed in the United States in 1921. A further advance was a French patent issued in 1930 (O. Wüst), which proposed the treatment of foods with ionizing radiation as a method of controlling bacteria. None of these initiatives led to practical applications since no radiation sources with proper dose-rates were available before World War II.

After this period the situation changed when, parallel to the renewed interest in food irradation, the first powerful electron accelerators were built. In a research program on the use of ionizing radiation to preserve foods, the U.S. Atomic Energy Commission also developed powerful γ sources. After it had become increasingly clear that spent fuel assemblies from nuclear reactors are unsuitable for food irradiation, several U.S. universities installed the first ^{60}Co sources at the beginning of the 1960s. Extensive development of food irradiation by the U.S. Army in the 1950s, culminating in the establishment of a large army food irradiation laboratory at Natick, Massachusetts, in 1961 – 1962, also led to early studies along the same lines in many other countries as early as the 1950s.

The first commercial use of food irradiation took place in the Federal Republic of Germany in 1957, when a spice company near Stuttgart began irradiating its products with electrons from a Van de Graaff generator. This plant had to be shut down in 1959 when new legislation banned the treatment of foods with ionizing radiation.

In 1966 the first international symposium on food irradiation was held in Karlsruhe by the IAEA. At that time, the irradiation of a few foods was permitted only in Canada, the United States, and the former Soviet Union, but the food industry was not taking advantage of such approvals. An international project to identify any health risks involved in consuming irradiated foods was started in 1970. More than 20 countries took part in this study which was carried out under the auspices of IAEA, FAO, OECD, and WHO. In November 1980, an FAO – IAEA – WHO committee of experts stated that food irradiation up to doses of 10 kGy is generally unobjectionable from the toxicological standpoint [175]. Given this assessment, it was only logical that the committee did not deem further toxicological studies of irradiated food necessary. Since the recommendation of these international agencies, the number of approvals of irradiated foods has been growing year by year. Accompanying this trend is a steady growth in the use of the method in food technology.

2.4. Effects of Food Irradiation

2.4.1. Induced Radioactivity

High energetic ionizing radiation can initiate nuclear reactions. Such reactions do not occur below a certain threshold energy, and the energy of γ-rays from ^{60}Co and ^{137}Cs sources is too low to produce radioactive substances in foods and feeds. Such an effect cannot be ruled out when higher-energy X-rays and electron beams are employed. The total quantity, however, of induced radioactive substances, given the maximum energies and doses used for food irradiation, is several orders of magnitude less than the quantity of naturally radioactive substances always present in foods. Accordingly, induced radioactivity is not significant for food irradiation.

2.4.2. Chemical and Sensory Changes

Irradiation causes chemical changes in the treated foods and feeds. Much is known about the substances produced and about the factors

that influence the formation of radiolysis products, such as temperature, moisture, and the effect of oxygen. The most important factor is the radiation dose. At the low doses used to control insects in grain (< 0.5 kGy), it is very difficult to detect chemical changes in the irradiated product. On the other hand, many chemical changes become detectable at higher doses in the range of a few kilograys.

An extremely important point should be kept in mind: In isolated form, food constituents such as amino acids, vitamins, and carbohydrates are severely attacked by irradiation; they suffer less damage when treated with ionizing radiation in the complex and protective matrix of an intact food. In addition, most radiolysis products are not radiation-specific and are thus found in the unirradiated foods as well. For example, the irradiation of pure triglycerides generates hundreds of radiolysis products, but the quantity of any one component is so small that no significant toxicological potential can be attributed to these reactions – even though some of the products occurring are exceedingly harmful to health when present in higher concentrations. Cyclobutanones, produced when fats are irradiated, are one of the very few groups of substances now suspected to be formed solely by irradiation.

The chemical changes caused by irradiation can also lead to perceptible effects in flavor, smell, color, and texture. Some foods, for example, and some other dairy products are very sensitive to even low radiation doses. Even doses of ca. 0.1 kGy can cause a negative flavor change in milk, making it unacceptable to the consumer.

The treatment of *meat* with high radiation doses can also give rise to undesirable flavor changes. It appears that these changes occur in lean meat rather than fat. Pork is less subject to these changes than is beef or veal, presumably because of its higher fat content. The negative flavor changes are most marked just after irradiation, diminishing or vanishing after storage or during cooking. The changes are less pronounced at a low irradiation temperature. The color of meat can also change when it is irradiated. For all these reasons, radiation doses applied to meat generally do not exceed a few kilograys.

The upper dose limit for *fruits and vegetables* in practice is set by the strength of the plant tissue. Doses of 1 – 3 kGy are used, depending on the product, and many fruits become soft even at these doses. This is not a direct effect of the radiation but a physiological reaction, the breakdown of the cell membrane by enzymes. The softening is not immediately observed but begins hours and sometimes days after the exposure to radiation.

2.4.3. Changes in Nutritive Value

Detailed studies have shown that the metabolizable energy of macronutrients (carbohydrates, fats, proteins) is not affected by irradiation up to doses of 10 kGy and even far above this value. Essential amino acids, essential fatty acids, minerals, trace elements, and most vitamins suffer no significant degradation, provided the irradiation is restricted to foods suitable for this treatment and is performed in a controlled manner (e.g., sensitive products are irradiated at low temperature with at least partial exclusion of atmospheric oxygen). Some vitamins show great losses even under these conditions. An example is the roughly 30 % loss of vitamin B_1 when chicken meat is irradiated (dose 5 kGy, irradiation temperature − 15 °C). Such losses are not, however, greater than those occurring in other, generally accepted food-processing methods such as preservation by heat.

2.4.4. Effects on Microorganisms

Microorganisms, especially gram-negative bacteria such as *Salmonella*, can be killed by irradiation. The spores of bacteria, however, are killed only at higher doses; this means that botulism, a commonly lethal food-born illness, cannot always be prevented by irradiation.

Regardless of the number of microorganisms in food, a certain fraction of the microbial population is killed by a given radiation dose. It follows therefore that the number of microorganisms still present in the product after irradiation will be larger, the more organisms were present before the treatment. For this reason, irradiation (like any other food preservation technique) cannot replace good hygiene during food production and processing. Once spoilage has begun, irradiation cannot reverse it.

The degree of destruction of microorganisms depends, as do many other radiation effects, on

a number of factors, one of which is the temperature during the radiation treatment. Microorganisms become more sensitive to radiation at elevated temperature. Many organisms also become easier to control if the moisture content in the food is high.

Concerns that irradiation might produce radiation-resistant microorganisms or other dangerous mutations have not been eliminated. All experimental studies indicate that microorganisms surviving radiation treatment are injured and then react more sensitively to factors known to have negative effects on microbial growth. In other words, surviving microorganisms are more easily destroyed in cooking.

Approximate radiation doses (kGy) needed to cut the viable populations of various microorganisms by a factor of a million are listed below [165]:

Gram-negative bacteria	
Escherichia coli	1.5 – 3.0
Salmonella spp.	3.0 – 5.0
Shigella spp.	1.0 – 2.0
Acinetobacter spp.	0.5 – 1.0
Pseudomonas spp.	0.5 – 2.0
Proteus	0.5 – 1.0
Vibrio parahaemolyticus	0.5 – 1.0
Moraxella	5.0 – 7.0
Gram-positive bacteria	
Bacilli (vegetative forms)	2 – 3
Bacillus cereus	20 – 30
Bacillus stearothermophilus	10 – 20
Clostridium botulinum A and B	10 – 30
Clostridium botulinum E	10 – 20
Clostridium perfringens	20 – 30
Leuconostoc	0.5 – 3.0
Lactobacillus	2.0 – 7.5
Micrococcus spp.	2 – 5
Micrococcus radiodurans	30
Micrococcus roseus	30
Staphylococcus aureus	0.5 – 5.0
Streptococcus	5.0 – 7.5
Streptococcus faecalis	10 – 20
Molds and yeasts	
Aspergillus	1.5 – 5.0
Penicillium	0.5 – 2.0
Saccharomyces	5 – 10
Viruses	
Various types	30
Foot-and-mouth disease	10 – 30

2.4.5. Toxicological Consequences

Many toxicological studies of irradiated foods have been carried out since the 1950s. Foods on which toxicological investigations have been performed are listed in the following [165]:

1) *Fruits:* Apples [b]; apricots [a]; bananas [a]; dates [c]; tangerines (mandarins) [b]; mangoes [c]; oranges [a]; papayas [c]; peaches [a]; plums [b]; strawberries [c]
2) *Vegetables:* Carrots [a]; celery root [a]; cauliflower [a]; lettuce [a]; meadow mushrooms (champignons) [b]; onions [c]
3) *Grains:* Corn (maize) [a]; rice [c]; wheat [c]
4) *Legumes:* Beans [b]; lentils [a]; peas [b]
5) *Spices and prepared spices:* Garlic (powder) [a]; mixed spices [b]; onion (powder) [b]; paprika [b]; pepper (black) [b]
6) *Miscellaneous plant-derived foods:* Cacao (cocoa) beans [b]; potatoes [c]; walnuts [a]
7) *Fish and fish products:* Carp [a]; catfish [c]; codfish [c]; fish paté (kamaboko) [c]; flounder [b]; herring [b]; mackerel [c]; haddock [c]; plaice [b]; European trout [a]
8) *Shellfish:* Soft calm (gaper) [b]; shrimp [b]
9) *Meat* [d]*:* Bacon [c]; beef and beef products [c]; prepared foods containing meat [b]; ham [c]; horse meat [b]; Mixed offal [b]; pork [c]; poultry [c]

[a] This food has not been extensively tested.
[b] This food has been less thoroughly tested; normally, no long-term study has been performed.
[c] This food has been thoroughly tested; one or more long-term studies have been performed.
[d] Some of the studies considered were performed for special purposes with very high radiation doses.

While most of these studies do not point to special risks of irradiated foods, some authors have published alarming results. The main problem areas relate to observations on children and to feeding tests with rats, mice, and monkeys, which have indicated a slightly increased incidence of polyploidy in bone marrow cells or peripheral lymphocytes after the children and animals had been fed with freshly irradiated wheat (< 1 kGy) for several weeks. These changes did not, however, occur when the wheat had been stored for about three months after the radiation treatment. Other authors have not confirmed these findings, so that nowadays most toxicologists do not accept the argument that polyploidy results from the consumption of irradiated food.

In contrast, there are many extensive studies that support the conclusion that irradiated foods

are unobjectionable from the health standpoint. In a French study, for example, nine radiolysis products identified in irradiated starch were fed daily to rats in a quantity 800 times the presumed rate of intake given normal daily consumption of irradiated starch. No detrimental effects could be found.

The fraction of irradiated food in most animal feeding experiments has been 30 % of the daily diet. In several studies, multiple generations of animals were raised on an exclusive diet of irradiated feed. Neither carcinogenic nor other toxic effects were observed.

A US study with irradiated chicken meat is important because of the scope of research and the high dose administered (58 kGy). Dogs, mice, and fruit flies were fed on irradiated meat, on heat-sterilized meat, and on enzyme-inactivated meat. Although the dose was far higher than is permitted for the irradiation of chicken meat (max. 10 kGy), no detrimental effects of the radiation treatment were found.

A study in the People's Republic of China, in which volunteers consumed various irradiated foods over a period of 7 – 15 weeks, also showed no negative health effects and no chromosomal damage.

2.5. Regulations on the Irradiation of Foods and Feeds

2.5.1. The European Community

Because the member countries of the European Community have widely varying laws governing the irradiation of foods (only Belgium, Denmark, France, Italy, The Netherlands, Spain, and the United Kingdom permit the irradiation of some foods, and not the same foods), the EC is attempting to create a unified regulation. What compromise will be arrived at cannot yet be foreseen, since the question of permitting irradiated foods is disputed not just between the member countries but also between the Commission of the European Communities in Brussels and the European Parliament. While countries such as the United Kingdom and France, together with the EC Commission, seek a relatively broad approval of irradiated foods, other member countries such as Luxembourg, Denmark, and Germany, with the European Parliament, oppose more liberal approval of irradiation and wish either to allow the irradiation of spices and dried vegetables only, or else to dispense with this type of food processing altogether.

2.5.2. Federal Republic of Germany

As of the end of 1992, the Food and Commodities Act (Lebensmittel- und Bedarfsgegenständegesetz, § 13 LMBG) prohibited the sale of *foods* treated with ionizing radiation. No use has been made of the possibility – allowed for in the Act – of gaining approval for the irradiation of foods either through regulatory proceedings or by the granting of variances (except as allowed for monitoring and measuring purposes by the Food Irradiation Regulation of December 19, 1959, as amended up to May 16, 1975). On the international level the federal government has pressed and continues to press for a complete ban on food irradiation.

The creation of the European common market on January 1, 1993, changed this situation. Under the Act to Modify the Provisions of Legislation on Veterinary Medicine, Foods, and Animal Husbandry (Gesetz zur Änderung veterinärrechtlicher, lebensmittelrechtlicher und tierzuchtrechtlicher Vorschriften) passed on December 18, 1992, irradiated foods lawfully produced in another member country of the European Community and lawfully traded there, or originating in a third country and lawfully traded in a member country of the European Community, may be introduced into Germany and traded there. Any person who whishes to place the irradiated food on the market in Germany must, however, apply to the agency having jurisdiction, the Federal Ministry for Health in Bonn, for permission to do so. In case of an affirmative decision, such decision is announced in the Bundesanzeiger (official gazette); any permission is to be linked with an appropriate labeling requirement.

As in virtually every country in the world, the irradiation of animal *feeds* is permitted in the Federal Republic of Germany.

2.5.3. Other Countries

In addition to the EC member countries listed, some 30 other countries permitted the irradiation

of certain foods in the 1980s. These include Argentina, Brazil, Canada, Chile, the People's Republic of China, Hungary, India, Israel, Japan, Poland, South Africa, Thailand, and the United States.

2.5.4. International Organizations

The WHO, FAO, and the IAEA advocate the irradiation of food. The three international agencies promote the use of food irradiation all over the world; the IAEA, above all, has supported applied research in this field, especially with the participation of developing countries. The WHO also takes an active role in informational efforts aimed at gaining acceptance for food irradiation. One example is the WHO brochure [164]; another comes from WHO's 10 Golden Rules for hygienic food preparation, in which Rule 1, "Do not eat certain foods raw," is followed by the text, "If you have the choice, you should use fresh or frozen poultry that has been treated with ionizing radiation."

2.5.5. Consumers

Food irradiation will find wider use only when products treated in this way are also accepted by the consumer. Predicting consumer reaction, however, is quite difficult, and so market tests have been performed in some countries for many years. Consumers are offered some properly labeled irradiated foods in comparison with unirradiated products. No such large-scale studies have yet been carried out in Germany. One IAEA summary of 1984 – 1990 market research on irradiated foods states that some 40 distinct irradiated products were offered to consumers in 13 countries over this period. Some 7000 t of irradiated products were test-marketed in this way. In most of the studies reported, a majority of consumers either preferred the irradiated products on account of their higher quality or at least expressed no reservations about purchasing them.

Consumer organizations in quite a few countries (including Germany) oppose food irradiation, sometimes vehemently. The cited studies, however, show that these organizations may take a much more critical view of food irradiation than are the individual consumers.

2.6. Industrial Irradiation of Foods and Feeds

2.6.1. Irradiation Plants (see also → Radionuclides, Chap. 5.1.3., → Radionuclides, Chap. 5.1.5.)

Food irradiation plants varies in design and physical operations performed, depending on the intended purpose. There are essentially tow classes, batch and continuous. In systems operating *batchwise*, a certain quantity of food is irradiated for a definite time. The irradiation cell is then unloaded and recharged. In a *continuous irradiation system*, the food is conveyed around the source at a certain speed in order to ensure that all the food receives the same desired dose. Batch systems are simpler in design and more flexible than continuous ones. Continuous systems, on the other hand, can handle large volumes of products, especially when an individual product must be treated with a set dose. The food-processing industry prefers continuous treatment for economic reasons.

Food irradiation ordinarily involves radiation doses of 50 Gy to 10 kGy, depending on the kind of food and the effect desired.

2.6.2. Costs

Costs of food irradiation range from a few cents to around \$ 0.75 per kilogram. This wide variation results from the many factors involved in the irradiation process. These include, among others, the dose administered, the volume and kind of product, and the type and efficiency of the radiation source. Further, the costs depend on whether the system is designed to irradiate a single food or a variety of foods. Shipping and packaging costs are additional. The construction of an industrial system costs ca. \$ 7×10^6.

2.6.3. Present Level of Use

Complete data on the commercial use of food irradiation in the *EC member countries* are unfortunately not available. With respect to quantity, France and The Netherlands were the leading users in 1990, with about 20 000 t each,

followed by Belgium with ca. 10 000 t (1988). The foods irradiated are mainly shrimp, poultry, frogs' legs, and dried foods such as spices, herbs, and powdered eggs. Outside the EC, irradiation is used principally in the *People's Republic of China*, with a total of ca. 40 000 t between 1984 and 1990, the leading product being a liquor made from sweet potatoes and garlic; *Japan*, with irradiation of ca. 15 000 – 20 000 t of potatoes per year; *South Africa*, with more than 20 000 t per year, chiefly fruits, spices, potatoes, dried vegetables, and onions; the *United States*, where the leading item is some thousands of tonnes of spices per year; and the former *Soviet Union* (Odessa, now Ukraine), with ca. 400 000 t of grain per year (disinfestation). In *Germany*, commercial irradiation of foods (except in scientific research) is permitted only for export and is practiced sporadically for this purpose. In the former German Democratic Republic, at least during one season, ca. 5000 t on onions for cooperative marketing were irradiated. The overall trend is toward increasing use.

The irradiation of *feeds* is commercially practiced in some countries, primarily in the breeding of laboratory animals. More exact information is lacking as to the quantities of feed irradiated.

2.7. Inspection of Irradiated Foods

Irradiated products must be monitored and inspected in several areas. Inspection the *irradiation plants* serves to maintain the prescribed treatment conditions, prevent the use of irradiation to replace hygienic practices in production, storage, and shipping, and prevent multiple irradiation. In *trade*, proper documentation either in accompanying papers or by labeling must be verifiable. Methods of detecting irradiated products are needed for this kind of control.

Tetsting and Analysis. Tests aimed at identifying irradiated foods were undertaken as early as the beginning of the 1960s. Truly successful methods, however, were not developed until the early 1980s. Work by the BGA in Berlin, for example, had the goal of detecting irradiated spices and dried vegetables with the aid of chemiluminescence and thermoluminescence tech-niques; this project led to the establishment of the first four official food inspection methods for irradiated products. Germany thus became the first country in the world to have officially acknowledged techniques for the detection of irradiated foods. Another method for irradiated bone-containing meat products was adopted in 1991: electron spin resonance spectroscopy (ESR). Other methods to follow shortly will enable the effective inspection of virtually any food that is a candidate for irradiation. In meat products not containing bone, the detection of certain hydrocarbons in the fat fraction makes it possible to state unambiguously whether the product has been treated with ionizing radiation. The method can also be applied to other foods with sufficiently high fat contents. Examination of fish bones and nutshells (i.e., water-poor constituents of foods) by ESR spectroscopy can reveal the irradiation of these products. Finally, the thermoluminescence technique can be applied to any food contaminated with minerals (e.g., sand) or containing crystalline minerals, such as spices, herbs, fruits, vegetables, and mussels (shells). Intensive work on other techniques is under way, and it can be expected that the range of containing crystalline minerals, such as spices, herbs, fruits, vegetables, and mussels (shells). Intensive work on other techniques is under way, and it can be expected that the range of inspection methods will be largely complete in some two years.

Germany continues to be a world leader in this field. The methods cited have been used in a number of countries to identify irradiated products unlawfully offered for sale.

1. Introduction

Heribert Luig

1.1. Nucleons

The term “radioactivity” refers to the transformation or decay of atomic nuclei, occurring spontaneously (i.e., with no external stimulus and at an unpredictable time) with the emission of radiation (high-energy quanta or particles). This process is also called the radioactive decay of radionuclides. Radionuclides have to acquire the excess energy required for spontaneous decay. This energy comes from one of three sources:

1. As a result of nuclear fusion; the process that has created the nuclei of the elements (natural radioactivity)
2. As a result of activation by natural ambient radiation, especially cosmic rays (natural radioactivity)
3. Through artificial activation or nuclear fission (artificial radioactivity)

Atomic nuclei (nuclides) consist of nucleons. A given type of nucleus consists of a specific number of nucleons. Nucleons are bound together by an attractive force called the strong interaction force (strong force) or nuclear force. This strong force is one of the four fundamental interactions: strong force, weak force, electromagnetic force, and gravitation.

The *strong force* is characterized by a limited range that, logically, corresponds to a nuclear diameter, roughly 10^{-13} cm. Outside this range, the strong force is equal to zero.

There are two types of nucleons; protons (p) and neutrons (n). Protons and neutrons are referred to as elementary particles. According to results from high-energy physics, however, these are not simple but structured systems. Their structural components consist of three quarks. The quarks that make up nucleons exist in two different forms, “up” (u) and “down” (d). Protons and neutrons have the following make-up:

p: (uud)
n: (udd)

The strong force acts directly between quarks, but indirectly between nucleons. Quarks bear electric charges.

The charge of the up quark: + 2/3 (positive) elementary charge. The charge of the down quark: – 1/3 (negative) elementary charge.

On balance, the proton has a single positive unit of charge whereas the neutron appears electrically neutral. The two types of nucleons are therefore similar. If a down quark in a neutron is replaced by an up quark, a proton is obtained. This is what takes place in β decay:

$$\mathrm{d} \rightarrow \mathrm{u} + \mathrm{e}^- + \bar{\nu} \tag{1.1}$$

In the transformation of a down to an up quark, the down quark emits an electron (e^-) and an antineutrino ($\bar{\nu}$).

From the viewpoint of the neutron, or of the nucleus balancing its nucleons, the process can be described as:

$$\mathrm{n} \rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu} \tag{1.2}$$

The β decay process is governed by the *weak interaction*.

β Decay, or more correctly, the β transformation of the neutron, is an exothermic process. A free neutron (i.e., one not bound to other nucleons) has a mean lifetime of 930 s. In the terrestrial environment, however, a free neutron scarcely ever reaches the end of its life-time — apart from the fact that there are hardly any free neutrons — because, attracted by the strong force, it quickly attaches itself to an atomic nucleus as an additional nucleon. This process is called *neutron capture*, a name reflecting the viewpoint of the absorbing nucleus.

Nucleons do not form some kind of perpetual motion system. The inverse process, in which a proton changes into a neutron, is not exothermic. The free proton, the hydrogen nucleus, is stable.

Accordingly, the β transformation of the proton can be described as:

$$\mathrm{p} + \mathrm{e}^- \rightarrow \mathrm{n} + \nu \tag{1.3}$$

A proton incorporates an electron, a neutron is formed, and a neutrino is emitted. The above relation describes the β decay of the proton by *electron capture*. A proton in an atomic nucleus preferentially incorporates an orbital electron from the K shell, because K electrons have the highest probability of being present at the location of the nucleus. The β decay of the proton is described as:

$$\mathrm{p} \rightarrow \mathrm{n} + \mathrm{e}^{+} + \upsilon \tag{1.4}$$

Here a proton is transformed into a neutron, emitting a positron (an electron with a single positive charge — the "antiparticle" of the electron) and a neutrino. This process is energetically possible only in a nucleus whose energy is greater than the energy of the product nucleus by at least twice the rest-mass energy of a positron (= 2×511 keV), for according to Dirac's theory, the antimatter particle (the anti-electron) must be raised from the negative to the positive energy state that characterizes the surrounding matter.

The nuclear event governed by the weak interaction, generally called β transformation or β decay, thus occurs in three forms:

1. With emission of an electron (β^{-})
2. With emission of a positron (β^{+})
3. With capture of an electron (β^{+})

General Remarks on Nucleons. Neutrons and protons have approximately the same mass. The neutron is slightly, but crucially, heavier; according to Einstein's equivalence between mass and energy, the mass of the neutron is larger by an amount that is equivalent to the energy difference linked with the spontaneous exothermic conversion of a neutron to a proton.

Mass of proton. 938.2 MeV
Mass of neutron. 939.6 MeV

Both species of nucleons have an intrinsic angular momentum, spin 1/2; they are therefore subject to Pauli's exclusion principle as are the spin –1/2 electrons in the atomic shell; and, like the electrons, move along orbits having well-defined angular momenta, in "shells." The shell model of the atomic nucleus is described in Section Nuclides and Radionuclides. Both the proton and neutron have a magnetic moment; this is expected in the case of the proton and, in the case of the neutron, plausible because of the three-quark structure.

Essentially, a nuclide (an atomic nucleus) is uniquely characterized by the number *Z* of protons (*Z* = atomic number in chemistry) and the number *N* of neutrons. The total of these is *M*, the mass number of the nucleus:

$$M = Z + N \tag{1.5}$$

just as in chemistry an element is characterized by the number *Z* of orbital electrons.

An atom is said to be in an excited state if not all of its electrons are located in the lowest possible shells. Similarly for the nucleus: It is in an excited state if a neutron or proton is in a higher shell, otherwise it is in the most favored lowest-energy state known as the ground state. In addition to single-nucleon excitation, the nucleus can also be in a state of "collective" excitation, which consists of the rotational or vibrational states of all the nucleons collectively.

In an excited atom, if an electron from a higher shell drops into the free orbital position, a photon (X-ray quantum) or another orbital electron (Auger electron) is ejected.

In an excited nucleus, each nucleon that has acquired an "unduly" high energy drops back into its lower-energy position; the energy liberated is again emitted, either in the form of a photon (γ quantum) or an orbital electron (conversion electron). In "internal conversion", K conversion (with a conversion electron from the K shell) is again preferred (similarly to the β transition by electron capture), because K-shell electrons have the highest probability of being present at the location of the nuceus and thus falling victim to the energetic process involved in the restructuring of a nuclide.

The events in a γ transition are governed by the *electromagnetic force*. There are plenty of charged particles in the nucleus, since three quarks form one nucleon.

Usually, nuclides remain in a given excited state for only a short time. A state that is "longer-lived" from the metrological or other viewpoint is said to be metastable. For example, the symbol ^{99m}Tc denotes a nucleus with 43 protons and 56 neutrons in an excited state, in this instance 142 keV above the ground state. It also has a longer lifetime; in this instance, a half-life of 6.03 h.

The term "metastable" now survives only in the "m" of the symbol. The longer-lived state is usually called an *isomer*, by analogy with the term in chemistry: a different chemical structure with same empirical formula corresponds here to a different nuclear structure with identical constituents (*Z* protons and *N* neutrons).

The last process to be described is α *decay*. This type of decay, which happens only to heavy nuclei consisting of at least 144 nucleons (^{144}Nd being the lightest α-emitting nuclide), involves the spontaneous emission of a helium nucleus.

1.2. Timeline of Discoveries in Radioactivity

1896: Discovery of Radioactivity. H. BECQUEREL discovered radioactivity one year after the discovery of X rays. Using photographic plates to study the fluorescence of uranium compounds, BECQUEREL found that uranium blackened plates even after a long period in the dark. Fluorescence, therefore, cannot be the cause of the blackening; the radiation comes spontaneously from the uranium, without prior excitation.

Radio-Thorium. MARIE CURIE made a systematic study of all elements to investigate which ones emit the newly discovered radiation. She discovered that thorium, two atomic numbers away from uranium, is also "radioactive."

First Activity Unit, the Curie (Ci). In quantitative investigations with a galvanometer, M. CURIE found that the intensity of the radiation from uranium (the radioactivity) is proportional to the quantity of uranium.

1898: Polonium. From the pitchblende ore of a uranium deposit, M. CURIE isolated an element with atomic mass 210. She proposed the name "polonium" after her homeland.

1898: Radium. PIERRE and MARIE CURIE found element 88 in pitchblende from Joachimsthal and named it "radium."

1899: Birth of Nuclear Physics. ELSTER and GEITEL stated the hypothesis that radioactivity originates from the transmutation of elements. This hypothesis has ultimately become the basis for nuclear physics.

1899: Alpha and Beta Radiation. By measuring ranges, RUTHERFORD determines that radioactive radiation consists of at least two distinct components, which are designated α and β.

1903: Nobel Prize for Research on Radioactivity. H. BECQUEREL, M. SKLODOWSKA-CURIE, and P. CURIE shared the Nobel Prize for Physics.

1903: Gamma Radiation. The third component of radioactivity, called γ radiation, was first reported in 1903 and later described in 1906 by P. VILLARD.

1905: Gamma Quanta. EINSTEIN postulated the existence of corpuscular light quanta (photons) and explained the photoelectric effect. Einstein's postulate also explains the character of γ quanta.

First Decade of the 20th Century: Identification of Alpha and Beta Particles. The α *particle* was identified in 1903 by DES COUDRES, who determined the ratio of mass to charge of this particle, and in 1908 E. REGENER measured the charge. The α particle is found to have a mass identical to that of the helium nucleus. This result supplements the observation made by RAMSEY and SODDY (1903) that the noble gas helium is generated from "radium emanation"; this observation in turn supports ELSTER and GEITEL's 1899 thesis of transmutation. In 1909, RUTHERFORD also showed by spectroscopic measurements that α particles are helium nuclei.

For β *particles*, the deflection in electric and magnetic fields gives the ratio of charge to mass (KAUFMANN) and showed that the specific charge is the same as that of cathode rays, i.e., electrons.

1906: Equivalence of Mass and Energy. EINSTEIN stated that mass and energy are equivalent and can be transformed into each other. This equivalence is fundamental to all phenomena of radioactivity and nuclear physics.

1907: Three New Radioactive Elements. OTTO HAHN discovered the radioactive elements radiothorium, radioactinium, and "mesothorium" I and II.

1909: Isotopy. F. SODDY reported that lead atoms have different masses. The phenomenon of isotopy had not yet been explained until the discovery of the neutron in 1932.

1911: Second Nobel Prize for M. SKLODOWSKA-CURIE. M. SKLODOWSKA-CURIE received the Nobel Prize in Chemistry for the discovery of radium and polonium.

1911: The Atomic Nucleus. Rutherford's model of the atom has a small, heavy nucleus surrounded by a shell of electrons.

1913: Charge and Size of the Atomic Nucleus. H. GEIGER and E. MARSDEN obtained experimental confirmation of the Rutherford atomic model by measuring the charge and size of nuclei.

1913: The Hydrogen Atom; Planck's Constant. NIELS BOHR described a planetary model of the atom. The spectral lines of the hydrogen atom were calculated with the help of Planck's constant.

1918: Protactinium. O. HAHN and L. MEITNER discovered the radioactive element protactinium.

1919: Discovery of the First Artificial Nuclear Reaction. While studying the range of α particles in nitrogen, RUTHERFORD observed components having a longer range but a lower signal intensity on the scintillation screen. RUTHERFORD interpreted these unexpected components as protons:

$$^{14}N + \alpha \rightarrow {}^{17}O + p$$

1923: Compton Effect. A. H. COMPTON showed that X-ray quanta collide with electrons like discrete particles (1927 Nobel Prize).

1925: Pauli Exclusion Principle. The exclusion principle of W. PAULI, which holds for particles with spin 1/2 and thus in particular for electrons in the atomic shell, explains the periodic system of the elements. It has also accounted for the nuclear systematics in the framework of the shell model. Protons and neutrons are also spin –1/2 particles.

1926: Fermi Statistics. Fermi statistics apply to all spin –1/2 particles ("fermions"), thus in particular to electrons and nucleons.

1927: Chemical Bonding. W. HEITLER and F. LONDON accounted for chemical bonding on a quantum-physical basis.

1927: Betatron Principle. R. WIDERÖE and M. STEENBECK described the betatron principle for accelerating electrons.

1928: Spin and Magnetic Moment of the Electron. P. A. M. DIRAC explained the angular momentum and magnetic moment of the electron by introducing the laws of relativity theory to extend quantum wave mechanics.

1928: Heisenberg's Uncertainty Principle. HEISENBERG stated that in the world of elementary particles, position and momentum cannot both be determined simultaneously.

1930: Prediction of the Positron. In the framework of his extended quantum theory, DIRAC predicted the existence of the positron, which was discovered experimentally in 1932.

1930: Cyclotron. E. LAWRENCE constructed the cyclotron.

1932: Discovery of the Positron. C. D. ANDERSON discovered the positron.

1932: Discovery of the Neutron. JAMES CHADWICK discovered the neutron. Nuclei consist of neutrons and protons.

1932: First Artificially Induced Nuclear Reaction. The first nuclear reaction initiated by artificially accelerated particles (150 keV protons) was accomplished by J. D. COCKROFT and E. T. S. WALTON. They received the Nobel Prize in 1951.

1932: Deuterium. H. C. UREY discovered deuterium (Nobel Prize 1934).

1932: Pair Production. I. CURIE and F. JOLIOT discovered pair production with the postulate that a γ quantum transforms into an electron – positron pair; mass and energy are equivalent (EINSTEIN, 1906).

1934: Annihilation Radiation. THIBAUD and JOLIOT discovered the emission of annihilation radiation when a positron and an electron interact and subsequently produce two γ quanta. As in the case of pair production, mass and energy are equivalent (EINSTEIN, 1906).

1934: Artificial Radioactivity. I. CURIE and F. JOLIOT discovered artificial radioactivity.

1934: Neutron-Induced Nuclear Reactions. E. FERMI initiated nuclear reactions with neutrons.

1934: Neutrino Theory. E. FERMI postulated the existence of the neutrino in order to account for β decay.

1935: Betatron. M. STEENBECK constructed the betatron, an electron accelerator.

1937: The μ Meson. The μ meson, predicted in 1935 by YUKAWA, was discovered in cosmic rays.

1937: Technetium. G. PERRIER and E. SEGRÉ discovered element 43, technetium, as a nuclear reaction product. Because its half-life of 4.2×10^6 a (^{98}Tc) or 210 000 a (^{99}Tc) is short on a cosmological scale, the element has never been found in nature. It is, however, certainly present in nature as a product of the very rare spontaneous fission of uranium.

1938: Neutron-Induced Nuclear Fission. HAHN and STRASSMANN discovered that the uranium nucleus can be induced to fission by neutron bombardment.

1942: Chain Reaction. E. FERMI achieved the first nuclear chain fission reaction.

1945: Synchrotron. E. M. MCMILLAN and V. VEKSLER developed the synchrotron principle.

1950: High-Energy Accelerators. In 1950 there were 10 accelerators producing particles with energies of 100 MeV or higher.

1954: 5 GeV Protons. The "bevatron" in Berkeley accelerated protons to an energy of 5 GeV. The age of elementary-particle physics has now begun.

As this timeline shows, research on the atomic nucleus and radioactivity was far advanced by the 1950s. To list the advances of succeeding decades would go beyond the bounds of an introductory survey. The public has shown more interest in the engineering use of nuclear fission and the so-far unsuccessful attempt to obtain energy from nuclear fusion than in the results of basic research (⟶ Nuclear Technology). The theoretical understanding of nuclear physics has since been extended and is now being supplemented by knowledge of elementary-particle physics (high-energy physics), for example, what has been learned about the strong force that governs the interaction between nucleons, or about the weak force that governs β decay.

1.3. Nuclides and Radionuclides

A nuclide is a structured, dynamic assemblage of nucleons forming a stable combination. A radionuclide is, similarly, a structured, dynamic assemblage of nucleons but has the capability of spontaneous change.

Production of Radioactive Nuclides. The majority of radioactive nuclides on Earth — now more than 1500 — have been produced *artificially* (see Chap. Production of Artificial Radionuclides). The number per se is not really important, since it is subject to almost arbitrary increase. There is a large stock of ions that can be accelerated to high energies and aimed at one of a long list of targets, initiating a nuclear reaction. Many of the nuclei produced in such reactions have extremely short lifetimes, typically, the shorter the lifetime the more the reaction product differs from a stable nucleus.

Without human intervention, radionuclides are produced on Earth by *cosmic-ray species*: high-energy protons, mesons (entities consisting of two quarks), γ quanta, or electrons. In particular, activation of stable elements in the atmosphere and crust yields the radioactive nuclides ^{14}C, ^{3}H, and ^{10}Be. These undergo β^- decay toyield the following products: ^{14}C to ^{14}N (half-life 5730 a), ^{3}H to ^{3}He (12.323 a), and ^{10}Be to ^{10}B (1.6×10^{6} a).

Primordial Radionuclides. These nuclei originated in the early life of our universe and today, under terrestrial conditions, provide evidence of the occurrence of nucleosynthesis.

There are many theories, some competing and some possible supplementing others, about what happens in nucleosynthesis. All these theories, however, agree on one key point: that the heavier nuclei arose from lighter nuclei while the very light nuclei were produced by the fusion of single nucleons. Whether the very light nuclei, such as ^{4}He, were born as a direct result of the “Big Bang” or created in stellar interiors (as is thought to have happened for most of the elements), these controversial questions go beyond the scope of this article.

Figure 1 gives a two-dimensional scheme of all the primordial nuclides still present in the Earth's crust, broken down into the number of protons and number of neutrons. It is striking that the heavier primordial nuclei have more neutrons that protons and that the margin steadily increases. This “neutron excess” will be discussed further on. ^{42}Ca is the heaviest primordial nucleus with no neutron excess.

Figure 1. All the primordial nuclides still present in the Earth's crust

Bars and Isobars. The two-dimensional representation of the nuclide chart exaggerates the difference between neutrons and protons. Accordingly, nuclear systematics will first be discussed from the viewpoint of the nucleus, that is, in a one-dimensional treatment based on a parameter called nucleon number (*M*).

In chemistry the term “element 10,” is used with unambiguous reference to the element having atomic number 10. The atomic number is equal to the number of protons. For the neutral element, the atomic number is also equal to the number of electrons in the atomic shell. This element 10, with the name neon, has an atomic mass of 20.179. This value arises from the fact that there are three stable isotopes of element 10, ^{20}Ne (with isotopic abundance 90.51 %), ^{21}Ne (0.27 %), and ^{22}Ne (9.22 %).

By analogy with the identification of chemical element 10, a nucleus consisting of 10 nucleons is called bar 10 (from Greek τό βάρος, which means weight). All nuclei having 10 nucleons are isobaric with one another. The stable bar 10 consists of five neutrons and five protons. It is the nucleus of element 5, boron. There is no other stable isobar 10, although there is a stable boron isotope ^{11}B; fewer isobars than isotopes exist. A given bar, as a rule, has either a single stable form or, in some cases, two stable isobars. This law follows from the possibility of β decay, which enables the bar to change a nucleon of one species into the other species. A bar always has this capability when the transformation is energetically possible; naturally, the conservation of angular momentum also governs any transformation. Thus every bar undergoes transforof angular momentum also governs any transformation. Thus every bar undergoes transformation until it reaches the energetically most favorable situation.

Bars with an Odd Number of Nucleons. Examine bar 99 from this standpoint. The bar has just one stable nuclide, ^{99}Ru, an isotope of element 44. Element 44 has no fewer than seven stable isotopes. Figure 2. lists the radioactive isobaric nuclei of bar 99. From ruthenium to cadmium (atomic number 44 – 48) the proton number increases by 1 and the neutron number decreases by 1 at each step. The ordinate is the mass difference between the respective isobar and the stable isobar (Ru). Since the sum of the masses of the nucleons changes little through an isobaric series, the equivalence of mass and energy means that larger mass corresponds with lower bindingenergy. The mass defect of the lightest nucleus in the series corresponds to a particularly high binding energy.

Figure 2. Mass or energy parabola of the isobars of bar 99

Among the isobaric nuclei of bar 99, why do elements 48 – 45 and 37 – 43 differ in binding energy from element 44? For a given bar with an odd number of nucleons, 99 in the present case, the positive binding energy is governed by the *strong interaction* between each of the 99 nucleons and (especially) its nearest neighbors, since the strong interaction acts over a short range.

The *electrostatic interaction* between protons is a repulsive force that lowers the binding energy. If only the electrostatic interaction is considered, the binding energy increases when a β^+ transformation changes one of its protons into a neutron. This happens to elements 48 to 45 of bar 99 (gain in binding energy). For quantum-mechanical reasons, however, an increase in the number of neutrons also carries an energetic disadvantage, which is described by the "nuclear shell model". In the nuclear field set up by all the nucleons as a whole, both protons and neutrons are located in individual orbits arranged in shells, similar to the configuration of electron shells in the central field set up by the nucleus. Because nucleons, like electrons, have an intrinsic angular momentum, spin 1/2, the Pauli exclusion principle dictates that each nucleon is located in a site that can be singularly occupied: No neutron can match another neutron in all the quantum numbers, and similarly no proton can match another proton.

In this way, every β^+ transformation causes a higher-energy neutron site to be occupied while releasing a lower-energy (energetically more favorable) proton site. On the other hand, such a transformation frees the nucleus of one positive electrical charge. These two effects are balanced for the stable nucleus with proton number 44, the element ruthenium. Elements 37 to 43 of bar 99 release a higher-energy neutron site upon a β^- transformation, but the electrostatic repulsion increases due to the proton that is produced. The masses of the isobars of bar 99 fall approximately on a parabola (mass or energy parabola), as shown in Figure 3. The sole stable isobar is located near the vertex of the curve. Odd-numbered bars have no more than one stable nuclide. The stable bar 99 has 44 protons (an even number) and 55 neutrons (an odd number), and so ^{99}Ru is said to be an even – odd nucleus. All the nuclei of the isobaric series 99 alternate between even – odd and odd – even. This law naturally holds for all odd bars.

Early in the study of stable-nucleus systematics, it was believed that five exceptions had been found to the rule that any odd bar has only one stable nuclide. The existence of these exceptions was later disproved: ^{87}Rb (half-life 4.8×10^{10} a; see Fig. 3), ^{115}In (4.0×10^{14} a), ^{187}Re (5.0×10^{10} a), and ^{113}Cd (9.0×10^{15} a) undergo β^- decay to their stable neighbors ^{87}Sr, ^{115}Sn, ^{187}Os, and ^{113}In. The fifth unconfirmed excep-tion, ^{123}Te, is transformed to stable ^{123}Sb by a β^+ decay with a half-life of 1.24×10^{13} a (Fig. 4). The β instability of these five nuclei was not detectable until the availability of advanced measurement techniques, because a long half-life is equivalent to a low transition probability and frequency. These nuclides are radioactive primordial nuclides, their production by nucleosynthesis, however, has left them in an energetic niche from which they escape only on an almost cosmological time scale. The continuing nucleosynthesis of the stable daughter nuclides ^{87}Sr, ^{115}Sn, ^{187}Os, ^{113}In, and ^{123}Sb can thus be witnessed.

Figure 3. The transformation of ^{87}Rb to ^{87}Sr through β^- decay

Figure 4. The transformation of ^{123}Te to ^{123}Sb through β^+ decay

Bars with Even Nucleon Numbers. Even bars from M = 36 up have two stable nuclides. This is a consequency of the pairing energy: The formation of very tightly bound neutron – neutron and proton – proton pairs results in a more favorable net nuclear binding energy. It can easily be shown that the isobars of an even-numbered bar alternate between even – even and odd – odd nuclei; the energies fall on two parabolas offset by roughly twice the pairing energy. Figure 5 shows the mass parabola for bar 138. ^{138}Ba and ^{138}Ce are stable, while ^{138}La is a primordial, naturally radioactive, odd – odd nuclide. It undergoes either a β^+ or a β^- transformation into one of its two stable neighbors; the net half-life is 1.35×10^{11} a. Figure 6 is a diagram of the corresponding situation for the primordial nuclide ^{40}K. Most nuclides lying on the mass parabolas in the figures — except the primordial nuclides — have been produced artificially.

Figure 5. Mass or energy parabola of the isobars of bar 138

Figure 6. The transformation of the primordial odd – odd nuclide ^{40}K through either β^- decay to the even – even isobar ^{40}Ca or through β^+ decay to the even – even isobar ^{40}Ar

So far, there are two exceptions to the rule that even-numbered bars from *M* = 136 upwards have two stable nuclides. The first is the stable odd – odd nucleus ^{50}V, the third stable species of its bar. It lies between the stable even –even isobars ^{50}Cr and ^{50}Ti. The second exception is bar 82 (Fig. 7), which has a single stable species, the even – even nucleus ^{82}Kr. Up until the 1970s, the primordial even – even neighbor ^{82}Se was regarded as stable for an obvious reason: It is now known that ^{82}Se decays by a double β^- process (simultaneous emission of two β^- particles) with a correspondingly long half-life of 1.0×10^{19} a, yielding the stable nuclide ^{82}Kr, which is located two places away. In other words, ^{82}Kr is another species whose nucleosynthesis is far from finished. The ^{82}Se (2 β^-) ^{82}Kr process has a very low probability of occurrence and is perceived as "against the rules," but its example confirms the trivial statement that the knowledge of nuclear physics and the laws that are regarded as governing it are correct only in the context of present measuring techniques and within a time "window" that is tiny when compared with cosmological spans of time.

Figure 7. The double β^- transformation of ^{82}Se to ^{82}Kr

Light bars (up to bar 35) have exactly one stable isobar, with two exceptions that have not yet been well explained by nuclear physics: There is no bar 5 at all, and bar 8 exists only in the form of artificially created unstable radionuclides.

α Decay. Within a given bar, there is a tendency to acquire states with the lowest possible energies and the strongest possible binding via the β process. While β decay is a local event in the context of nuclear systematics, governed mainly by the properties of the weak interaction and operating within a single bar, α decay involves the nuclear systematics of all bars and the mechanism of the strong nuclear force. An α decay takes place when a nucleus can become more stable by giving up some nucleons. The preconditions for this event should be understood in the framework of a collective model of all bars: the droplet model (Fig. 8). This model does not, however, include pairing energy; important for understanding the systematics of even bars.

Figure 8. Mean binding energy per nucleon *B/M* according to the droplet model

The droplet model does not hold for *M* < 40The binding energy is the result of the volume energy a, minus b, c, and da) Volume energy; b) Surface energy; c) Coulomb energy; d) Asymmetric energy; e) Binding energy

In the droplet model, the nucleons in the nucleus are treated as analogous to the molecules in a droplet of water. Every nucleon, whether proton or neutron, has the ability to take part in the strong interaction. Since the nuclear force essentially acts between quarks, the only bonds between nucleons are between nearest neighbors. Thus the binding energy of a nucleus is initially proportional to the number *M* of nucleons. In-side the nucleus, every nucleon takes up space, so that it is not incorrect to say that the volume of a nuclide is approximately proportional to the nucleon number (volume energy; see Fig. 8). The nucleons at the surface of a nucleus have, on average, fewer neighbors than those in the interior. Hence the surface (exterior) nucleons contribute less to the nuclear binding energy. Because the area : volume ratio becomes smaller with increasing volume (increasing nucleon number), nuclei with more nucleons have a more favorable area : volume ratio. Thus, in this respect, heavier nuclei are more stable than lighter ones, because the (negative) *surface energy* decreases.

Next, the contribution to binding energy due to the interactions already discussed is evaluated. *Electrostatic repulsion* between protons has a destabilizing effect and, accordingly, lowers the binding energy. Unlike the nuclear force, electrostatic repulsion acts over an unlimited range, so that every proton repels every other proton and is itself repelled. The destabilizing force of electrical repulsion is therefore proportional to $Z(Z-1)$, where Z is the number of protons. For Z "not too small," this is approximately a quadratic dependence, so that stable nuclei (as well as the primordial radiactive nuclei) have an increasing surplus of electrically neutral neutrons ("neutron excess"), which contribute to the stability of the nucleus with their nuclear force.

For the same quantum-mechanical reasons stated in accordance with the nuclear shell model, however, energetic disadvantages relate to the increasing number of neutrons. Additional neutrons occupy higher and higher energy levels, so that it is not possible to achieve stability through an "excessive" neutron excess (asymmetry energy). The contribution to nuclear stability due to an additional neutron grows smaller and smaller until it finally vanishes. The heaviest stable nucleus is ^{209}Bi.

Now if the net binding energy:

Binding energy = volume energy (nuclear force) + surface energy (negative) (nuclear force) + repulsion between protons (negative) (electrostatic) + higher energy of levels for excess neutrons (asymmetry energy) (quantum-mechanical)

is plotted versus the mean binding energy per nucleon bars starting around M = 70 – 80 appear to be less and less tightly bound. If the nucleus, however, could separate itself from a few nucleons, it would be more tightly bound. Some nuclei do take advantage of this possibility and expel a helium nucleus (α particle), which is very tightly bound. The lightest primordial α emitter is ^{144}Nd, which decays to ^{140}Ce and ^{4}He with a half-life of 2.1×10^{15} a. The heaviest primordial α emitter in the neighborhood of stable nuclei is ^{204}Pb which decays to stable ^{200}Hg with a half-life > 1.4×10^{17} a (Fig. 9).

Figure 9. The transformation of ^{204}Pb (82 p, 122 n) to ^{200}Hg (80 p, 120 n) through α decay

The heaviest primordial nuclides are the three isotopes of uranium (^{234}U, ^{235}U and ^{238}U) — whose radiation led to the discovery of radioactivity in 1896 — and ^{232}Th. The decay chains discussed in Chap. Radioactive Elements, Figure 18 begin from these four nuclides; each chain is a branching sequence of α and β^- decays, ending with isotopes of lead. There is also a low probability of the four primordial nuclides decaying by spontaneous *fission*; the products include, in particular, technetium. This element has formerly thought to exist on Earth only as an artificial product, but has reportedly been found in uranium ores.

1.4. The Law of Radioactive Decay

In a tennis game, the ball occasionally lands among the spectators. This is neither the point of the game nor the intent of the players; it is a random event in the dynamics of play. When it will occur cannot be predicted; there is merely a certain probability that it will happen.

Comparable with the dynamics of a tennis game are the internal dynamics of an individual radioactive nuclide, which lives with the permanent risk of losing, e.g., four nucleons (an α particle in this situation) all at once. The nuclide suffers this loss at an unpredictable time and without external stimulation. Radioactive nuclides undergo such changes spontaneously, and radioactive decay must be regarded as a stochastic process.

The behavior of the stochastic occurrence in time is characterized by a decay constant λ. This constant is defined as a probability per unit time, specifically the (infinitesimal) probability dw that a certain individual nucleus will decay in the infinitesimal time dt:

$$\lambda = \mathrm{d}w/\mathrm{d}t \tag{1.6}$$

or

$$\mathrm{d}w = \lambda\,\mathrm{d}t \tag{1.7}$$

The decay constant λ has the following properties:

1. It is equal for all nuclides of a given species
2. It is constant over time; Nuclides do not “age” and do not have any history

If a certain time interval with duration 1T is considered, the probability of observing the decay of a certain nucleus in T can be defined in the following way by analogy with Equation (1.7):

$$w\,(1\,T) = \lambda_{\mathrm{T}} T \tag{1.8}$$

If $\lambda_T T$ is the probability that the nucleus decays in the time interval T under consideration, then

$$w^{\circ}\,(1\,T) = 1 - w\,(1\,T) = 1 - \lambda_{\mathrm{T}} T \tag{1.9}$$

is equal to the probability that the nucleus will not yet have decayed after time 1T (that it will have “survived”). After two intervals of length T have passed,

$$\begin{aligned} w^{\circ}(2\,T) &= w^{\circ}(1\,T)(1-\lambda_{\mathrm{T}}) \\ &= (1-\lambda_{\mathrm{T}} T)(1-\lambda_{\mathrm{T}} T) \\ &= (1-\lambda_{\mathrm{T}} T)^2 \end{aligned} \tag{1.10}$$

after three intervals of length T,

$$\begin{aligned} w^{\circ}(3\,T) &= w^{\circ}(2\,T)(1-\lambda_{\mathrm{T}} T) \\ &= (1-\lambda_{\mathrm{T}} T)^3 \end{aligned} \tag{1.11}$$

and so forth. For any number n of intervals of length T, then:

$$w^{\circ}\,(n\,T) = (1-\lambda_{\mathrm{T}} T)^n \tag{1.12}$$

Equation (1.12) states that the probability w^o that the nucleus has not yet decayed is reduced by the same fraction λ_T in every equal time interval T. This kind of time dependence is described by an exponential function. The amplitudes of the time-dependent probabilities w^o (mT) at discrete times $t_m = mT$ lie exactly on the curve of an exponential:

$$w^o(mT) = e^{-\lambda mT}, m = 0, 1, 2, 3, \cdots, n, \cdots \tag{1.13}$$

If Equations (1.12) and (1.13) are combined, the result is:

$$w^o(mT) = (1 - \lambda_T T)^m = e^{-\lambda mT} \quad m = 0, 1, 2, 3, \cdots, n, \cdots \tag{1.14}$$

What does λ signify in the exponential function of Equation (1.4)? First, change from discrete time to continuous time t and write:

$$t = mT \tag{1.15}$$

It then follows that

$$m = t/T \tag{1.16}$$

so that Equation (1.14) becomes:

$$w^o(mT) = (1 - \lambda_T T)^{t/T} = e^{-\lambda t} \tag{1.17}$$

$$(1 - \lambda_T T)^{t/T} = e^{-\lambda t} \tag{1.18}$$

The next steps are simple mathematical transformations of Equation (1.18), in which the expression are taken to the limit of infinitesimal intervals T ($T \longrightarrow 0$).

Taking logarithms:

$$(t/T) \ln (1 - \lambda_T T) = -\lambda t$$
$$-\ln (1 - \lambda_T T) = -\lambda T$$
$$\ln (1 - \lambda_T T) = \lambda T$$

Inverting the logarithms:

$$(1 - \lambda_T T) = e^{-\lambda T}$$
$$\lambda_T T = 1 - e^{-\lambda T}$$

Series expansion of the exponential function:

$$\lambda_T T = 1 - \left[1 - \lambda T + (1/2)(\lambda T)^2 - \cdots\right]$$

or

$$\lambda_T T = \lambda T - (1/2)(\lambda T)^2 + \cdots$$

Division by T:

$$\lambda_T T = \lambda - (1/2)\lambda^2 T + \cdots \tag{1.19}$$

As the interval T becomes shorter and shorter, Equation (1.19) takes the following form in the limit $T \longrightarrow 0$:

$$\lim_{T \to 0} \lambda_T = \lambda \tag{1.20}$$

This shows that the decay constant λ defined in Equation (1.6) is immediately equal to the coefficient λ in the exponential function of Equations (1.17) and (1.18). Thus, for any time t,

$$\omega^o(t) = e^{-\lambda t} \tag{1.21}$$

Equation (1.21) states that the probability w^o (t) that a particular nucleus has not yet decayed after an “observation time” t will decrease exponentially with the decay constant λ as coefficient.

If now a group of identical radioactive nuclei are observed starting at a time $t = 0$ when the group consists of N individual nuclei, the probability is N (t)/N ($t = 0$) that there are N (t) undecayed nuclei after a time t:

$$N(t)/N(t = 0) = e^{-\lambda t} \tag{1.22}$$

This can be rewritten as:

$$N(t) = N(t = 0) \cdot e^{-\lambda t} \tag{1.23}$$

This exponential function describes the decrease in the number of radioactive nuclei that still remain to decay.

Consider now the time $t = \tau$ at which exactly half of all the nuclei have decayed (half-life):

$$N(\tau) = (1/2)N(t=0) \tag{1.24}$$

By Equation (1.23)

$$1/2 = e^{-\lambda t} \tag{1.25}$$

Manipulation of Equation (1.25) yields the following relations between the half-life τ and the decay constant λ:

$$\lambda - (\ln 2)/\tau \text{ or } \tau = (\ln 2)/\lambda \tag{1.26}$$

The number of radioactive nuclei is not accessible to measurement, but the rate of decaying nuclei, called the activity *A*, is.

Since λ is the decay probability of an individual nucleus in an (infinitesimal) time, if there are *N* radioactive nuclei then the expected number of decay events per unit time is:

$$A(t) = \lambda N(t) \tag{1.27}$$

If λ is expressed in reciprocal seconds (s^{-1}), Equation (1.27) gives the frequency in decay events per second, i.e., the activity *A* of a collection of radioactive nuclei (a "source").

In time-dependent notation, Equation (1.23) gives:

$$A(t) = \lambda N(t) = \lambda N(t=0)e^{-\lambda t} \tag{1.28}$$

$$A(t) = A(t=0)e^{\lambda t} \tag{1.29}$$

Equation (1.29) is the law of radioactive decay in its most frequently used form.

A comparison of Equations (1.21), (1.23), and (1.27):

$$w^o(t) = e^{-\lambda t}$$
$$N(t) = N(t=0)e^{-\lambda t}$$
$$A(t) = A(t=0)e^{-\lambda t}$$

shows that the probability $w^o(t)$ of a specific individual nucleus not yet having decayed (Eq. 1.21), the number $N(t)$ of decayable nuclei (Eq. 1.23), and the activity $A(t)$ (Eq. 1.27) display the same time dependence.

Definition of the Activity A. The physical quantity "activity" is defined as the number of decays per unit time. Since 1985, the unit of activity has been the number of decays per second:

$$A = \text{decays} \cdot s^{-1} \tag{1.30}$$

Its special name since 1985 has been the becquerel (Bq):

$$1\,\text{Bq} = 1\,\text{decay} \cdot s^{-1} \tag{1.31}$$

Up to 1950, the unit of activity was defined in terms of the activity of 1 g of uranium (special name: curie (Ci) after M. CURIE, who discovered the proportionality between the mass of radioactive uranium and the "intensity" of radiation). This definition was made numerically exact in 1950:

$$1\,\text{Ci} = 3.7 \times 10^{10}\,\text{decays} \cdot s^{-1} \tag{1.32}$$

By international convention, the unit curie may no longer be employed, but is, however, still frequently encountered. However, since radioactive decay is a stochastic process, sequential measurements of a radioactive source over time will not yield count rates $I(t)$ that correspond exactly to the exponential law $I(t) = I(0)\,e^{-\lambda t}$. The exponential law describes only the time dependence of the "expected" value $I(t)$. The individual measurements $\hat{I}(t_i)$ are Poisson distributed about the expected value $I(t_i)$. For "not too low" count rates $\hat{I}$ ($\hat{I} > 20$), typical of all technical uses of radioactive sources, the skew-symmetric Poisson distribution can be replaced, to a good approximation, by the symmetric Gaussian normal distribution.

1.5. Interaction between Radiation and Matter

1.5.1. *Interaction between Gamma Quanta and Matter*

γ Quanta (or, in general, photons), the quanta of the electromagnetic interaction, bear no charge and are thus not sensitive to the longrange electrostatic force of the nuclear charge or electrons.

γ Quanta in the energy range of nuclear transitions or the radiation following such transitions (roughly 0.01 – 10 MeV) are detected almost exclusively through three processes:

1. Compton effect on an electron
2. Photoeffect on a bound electron

3. Pair production in the field of a nucleus

Compton Effect. The Compton effect can be regarded as the inelastic scattering of a photon on an electron. In principle, Compton scattering can occur on either a free electron or a bound orbital electron. The photon undergoes a change in direction by an angle θ called the scattering angle and a loss of energy that depends on θ. If the initial photon energy is $h\nu$, the energy $h\nu'$ of the scattered photon is:

$$h\nu' = h\nu/[1 + \alpha(1 - \cos\theta)] \tag{1.33}$$

In Equation (1.33), α is the ratio of the photon energy $h\nu$ (in keV) to the rest-mass energy m_0 of the electron:

$$\alpha = h\nu/m_0c^2 = h\nu/511\ \mathrm{keV} \tag{1.34}$$

In the limit of very small angles ($\theta \longrightarrow 0$), the energy loss vanishes: $h\nu' \longrightarrow h\nu$. The largest energy loss occurs in "backscattering" (θ = 180°):

$$h\nu' = h\nu/(+2\alpha) \tag{1.35}$$

Thus a photon can never lose all of its energy in a Compton event and so can never disappear entirely.

By the law of conservation of energy, the energy lost by the photon is transferred to the electron in the collision:

$$E_{e1} = h\nu - h\nu' \tag{1.36}$$

By the conservation of momentum, the angle ϕ at which the electron is scattered is given by:

$$\cot\phi = (1 + \alpha)\tan(\theta/2) \tag{1.37}$$

The probability of an interaction between a photon and an electron is measured by the cross section of the electron. The cross section turns the interaction probability for some process into a geometrical relationship. The projectile, in this case the photon, is idealized as a body of infinitesimally small extent, i.e., a mathematical point. The other body in the interaction, in this case the electron, is modeled as a sphere. The radius of the sphere is selected so that, for given relative direction and position between the bodies, the process occurs with the same probability as a geometrical mechanical collision. The area of the plane projection through the center of the sphere defines the cross section.

The Compton effect cross section ${}_e\sigma$ of an electron is largest for low photon energies, decreasing very rapidly with increasing photon energy (Fig. 10). The direction distribution of the scattered photons is plotted versus primary photon energy in Figure 11.

Figure 10. The Compton effect

Figure 11. The angular distribution of Compton – scattered photons as a function of primary photon energy where $\alpha = E\ {}^{\sigma}/M_0C^2 = E\ {}^{\sigma}/511$ keV

Photoelectric Effect (Photoeffect). At energies below 0.1 MeV, the dominant interaction between γ quanta and matter having moderate to high atomic numbers is the photoelectric effect or photoeffect. This effect is the interaction with a bound orbital electron, in which the γ quantum gives up all of its energy to the electron in such a way that the photon disappears and the electron escapes from the atomic shell with a kinetic energy T described by the equation:

$$T = h\nu - B_e \tag{1.38}$$

where T is the kinetic energy of the electron and B_e is the electron binding energy.

By the conservation of momentum, a γ quantum cannot be "absorbed" by an unbound electron. Even in the atomic electron shell, the photoeffect in roughly 4/5 of all cases takes place on the most strongly bound electrons, those in the K shell. Of course, the energy of the γ quantum must be greater than the binding energy of the orbital electron for this to happen. This condition leads to a "K edge" in the curves representing the photoeffect cross section versus photon or γ energy for a given material.

If the γ energy drops below the K-shell binding energy of the absorbing material, the cross section decreases abruptly as K-shell electrons cease to be available as partners for the photoeffect (Fig. 12).

Figure 12. Energy dependence of the photoeffect

The directional distribution of orbital electrons after the absorption of a γ quantum (photoelectrons) depends on the photon energy. At low photon energies (ca. 0.01 MeV), the distribution has a peak nearly perpendicular to the initial photon direction; as the photon energy increases, the forward direction becomes more and more preferred. Figure 13 is a plot of the bipartition angle versus photon energy; this is the angle that exactly divides the frequency distribution of electron scattering angles in half. For example, the bipartition angle is just 20° at a photon energy of 1 MeV; this means that half of all photoelectrons have a direction less than 20° away from the photon or γ incidence direction.

Figure 13. Bipartition angle for photoelectrons as a function of primary photon energy

The conservation of momentum gives rise to an interesting observation. Because the photoelectron, having a rest mass, may absorb a large fraction of the energy of the zero-rest-mass photon in the form of kinetic energy, there is a large mechanical momentum in the direction of the photoelectron, and the nucleus must compensate for this by absorbing a recoil momentum.

The probability that a photon will experience a photoeffect on an orbital electron while pass-ing through a material is a function of the atomic number *Z* of the material and the energy $h\nu$ of the photon. The dependence is not a simple one.

Again, a cross section ${}_a\tau$ serves as a measure of this probability (where *a* denotes atom):

$$ {}_a\tau = \mathrm{const} \cdot Z^n/(h\nu)^m \tag{1.39} $$

where *n* in turn depends on $h\nu$ and *m* depends on both $h\nu$ and *Z*. Thus *n* and *m* are not constants. The complicated nature of the relation suggests that it is not the mathematical reflection of a well-known physical theory but a heuristic numerical expression. The value of *n* does not vary rapidly; roughly speaking, *n* = 4.05 ($h\nu$ = 0.01 MeV) while *n* = 4.6 ($h\nu$ = 3 MeV). Further, *m* is about 3 for $h\nu$ = 100 keV, 2 for $h\nu$ = 400 keV, and approaches unity at higher photon energies. For a constant photon energy, *m* increases slowly as the atomic number *Z* decreases.

Pair Production. At γ energies above 1.02 MeV, a third type of interaction called pair production becomes significant and ultimately dominant.

In pair production, the photon or γ quantum disappears altogether, and an electron – positron pair appears instead. The total energy of the elec-tron and positron is exactly equal to the initial photon energy:

$$ h\nu = (T_- + m_0c^2) + (T_+ + m_0c^2) \tag{1.40} $$

where *T* is the kinetic energy and m_0c^2 is the energy equivalent to the electron or positron rest mass. Both particles have exactly the same rest mass.

Pair production can occur only in the field of a charged particle, preferably of an atomic nucleus but potentially in that of an electron, since either nucleus or electron can absorb momentum and thus ensure is convervation.

The directions of the electron and positron are forward with regard to the photon direction, diverging symmetrically from the photon trajectory. As the photon energy increases, the divergence between the electron and positron paths decreases and the forward tendency becomes more marked.

While the cross sections for the Compton effect ${}_e\sigma$ and photoeffect ${}_a\tau$ decrease continuously with increasing photon energy, the cross section ${}_\alpha\kappa$ for pair production increases rapidly. At photon energies of a few MeV, pair production is the dominant process.

Linear Attenuation Coefficient and Exponential Attenuation Law for Photons. The linear attenuation coefficient is useful to describe the fate in macroscopic terms of photons as they pass through matter. This coefficient is nothing more than the three-dimensional cross-section density in the material.

The interaction partner of the photon in the Compton effect is a single electron. Consider the material having an atom density of *N* atoms per cubic centimeter and the atom having *Z* electrons. The cross-section density is then *NZ* and the

linear attenuation coefficient for the Compton effect is:

$$\sigma = {}_e\sigma\, NZ \tag{1.41}$$

For the photoeffect, the cross section is stated for a single atom. Accordingly,

$$\tau = {}_a\tau\, N \tag{1.42}$$

and likewise for pair production

$$\chi = {}_\alpha\kappa N \tag{1.43}$$

In the cross-section model, a three-dimensional element of the absorber having a volume of 1 cm^3 is thus filled by

$$NZ + N + N \tag{1.44}$$

spheres having diameters of ${}_a\tau$, ${}_e\sigma$, and ${}_\alpha\kappa$, respectively.

As the photon travels along its straight-line path, it does not “see” spherical obstacles but disks blocking its way. These disks have a total area μ per unit volume given by:

$$\mu = \sigma + \tau + \chi \tag{1.45}$$

Now μ is the total linear attenuation coefficient.

The probability d*W* that a photon will interact (hit a disk) while traversing an infinitesimal path element d*x* is equal to μ d*x*— the area covered by cross sections (perpendicular to the photon direction) — per unit area (1 cm^2):

$$\mathrm{d}W = \mu\,\mathrm{d}x/1 = \mu\mathrm{d}x \tag{1.46}$$

The probability $\mathrm{d}W_0$ that the photon travels a distance d*x* without a collision is:

$$\mathrm{d}W_o = 1 - \mathrm{d}W = 1 - \mu\,\mathrm{d}x \tag{1.47}$$

By analogy with the derivation leading to the exponential law of radioactive decay (see Section The Law of Radioactive Decay), the attenuation of a beam of initially *I* γ quanta over a path of length *x* will also be described by an exponential function:

$$I(x) = I(x = 0)\exp(-\mu x) \tag{1.48}$$

The exponential law applies only to a collimated beam, i.e., a collective of γ quanta having the same initial direction. Equation (1.48), in particular, makes no distinction between quanta that are completely lost by photoeffect or pair production and quanta that are merely removed from the primary ray bundle by Compton scattering. In this way, all γ quanta still considered to belong to the collimated beam still have their initial energy, so that the attenuation coefficient remains constant. This is an important prerequisite for the derivation of the exponential law. Equation (1.48) thus may describe an observation associated with a certain experimental setup rather than an especially significant physical law.

As will be shown in the following sections, the exponential attenuation law does not apply to charged particles (α, β). If one argued that α and β particles, as charged particles, were subject to the “hindering” effect of the electrostatic interaction with nuclear and orbital electron charges, this explanation would wrongly mix concepts from classical physics and quantum mechanics, and what is more it would presumably miss the point: γ Quanta have a very much lower interaction probability than α or β particles. If the volume were packed full of cross sections for γ quanta, they would not travel far; the idealization of exponential attenuation would never have been achieved. Thus the practical consequences are that shielding for γ quanta can never be as complete as for α or β particles and that the law of exponential attenuation is in many cases nothing but a good approximation.

1.5.2. *Interaction between Electrons and Matter*

The observed interactions are essentially electromagnetic in nature. The three most frequent types of interaction are as follows:

1. An inelastic collision takes place between the electron and a bound orbital electron. This is the dominant process; it results in the ionization or excitation of the atom to which the orbital electron belongs.
2. The electron collides inelastically with a nucleus. A bremsstrahlung quantum is emitted in this process.
3. Elastic scattering occurs on a nucleus. The electron undergoes a change in direction, no bremsstrahlung is emitted, but the electron loses energy so as to conserve momentum.

In an absorbing material, a fast electron is slowed and eventually comes to rest. It is a matter of change which of the above three processes occurs and where.

Because of the stochastic character of the processes, the individual members of an electron beam, even a beam of monoenergetic electrons, have quite different fates. The depth of penetration into the absorber can be expressed only as a distribution about a mean depth, called the mean range.

A quantity to be distinguished from the range is the *path length S* traveled by an electron in an absorber before the electron comes to “thermal” rest. The mean path length is several times the mean range (Fig. 14). As it passes through the absorber, the electron generates other high-energy electrons (δ electrons) by ionization.

Figure 14. Total path length *S* and range *R* of an electron traversing an absorber of thickness *d*

1.5.3. *Interaction between Positrons and Matter*

Positrons or β^+ particles are rare in natural terrestrial radioactivity. A *high-energy* (“*fast*”) *positron* interacting with matter initially experiences the same fate as an electron. When, however, the positron has lost its kinetic energy and comes to take part only in the thermal motion of its surroundings, its special property of being the antiparticle of the electron comes into play.

At first, the positron seeks as a partner an electron, with which it forms *positronium* (a hydrogen-like system in which the proton is replaced by the positron) for a vanishingly short time. The next event is the mutual annihilation of the electron and positron; the rest mass of both is converted to photons of corresponding energy, which are called “annihilation radiation.”

In virtually every case, positronium has total angular momentum 0 (S state, “parapositronium”). Accordingly, the annihilation of positronium yields two quanta of equal energy (511 keV each), which are emitted in exactly opposite directions. The annihilation of the very rare *orthopositronium* gives rise to three annihilation quanta.

1.5.4. *Interaction between Alpha Particles and Matter*

When fast heavy particles (i.e., particles whose mass is large compared to that of the electron, as is true for α particles) interact with matter (atomic nuclei and their electron shells; also in chemical compounds), the principal result is the ionization or excitation of the atoms. Elastic scattering on the nucleus and bremsstrahlung are negligible.

Naturally, α particles are more and more slowed down as they travel through matter. While in the initial portion of their path they chiefly ionize or excite the atoms present, at lower velocities an exchange of electrons takes place. The doubly positively charged helium atom can capture either one or two electrons, lose these electrons again, and also excite or ionize its surroundings.

The paths of α particles through matter are approximately straight lines. As a result, the energy-dependent range of α particles is a better-defined quantity than the range of electrons (Fig. 15).

Figure 15. The energy-dependent range of α particles

1.5.5. *Interaction between Neutrons and Matter*

Neutrons “almost never” occur in natural radioactivity. 1 g radium emits 1.7×10^{10} α particles a second, while a spontaneous fission releasing a neutron occurs just once every 10 min. For the sake of completeness (“almost never” is not “never”), some features of the interaction between neutrons and matter should be briefly outlined.

Neutrons are sensitive to the strong interaction but not to electric charges. Accordingly, neutrons passing through matter become involved in interactions when they come so close to a nucleus that the nuclear force comes into play. The neutron attaches itself to the collection of nucleons, thus becoming a new member of the collection. From the viewpoint of the nucleus, the nucleus captures the neutron. The cross sections for this process are accordingly called neutron capture cross sections.

The capture cross section depends on the atomic mass of the capturing nucleus: A greater atomic mass implies a larger nuclear volume and a higher probability that the neutron will hit the nucleus (there is no potential threshold), and hence a larger capture cross section. Further, the cross section depends on the neutron energy: The higher the energy, the faster the neutron moves, hence the shorter the interaction time and the smaller the cross section.

In the range of low neutron energies, the interaction probability can be described well by the statement that the capture cross section σ_n is inversely proportional to the neutron velocity v:

$$\sigma_n \sim 1/v \tag{1.49}$$

as Figure 16 shows. Resonances are super posed on this behavior if the neutron excites the nucleus to preferred higher-energy states.

Figure 16. Neutron capture cross section σ as a function of the neutron energy E_n for a natural isotope mixture of iridium (37.3 % ^{191}Ir, 62.7 % ^{193}Ir)

The nucleus, now with one more neutron, can become stable after γ transitions to the ground state; the process is then identified as an (n, γ) process. It may alternatively act as a "compound" or "intermediate" nucleus, undergoing β^- decay (typical of light and moderately heavy nuclei), α decay, or fission. The fission process is described by a separate fission cross section (⟶ Nuclear Technology).

These (n, γ) processes are naturally probable in elements having many closely grouped stable isotopes. Thus cadmium is as important for shielding of neutrons as lead is for shielding of γ quanta.

Along with neutron capture, *neutron scattering* (moderation) also occurs on nuclei; this process, sometimes going by many pathways, slows the neutron until its motion is the thermal motion of its surroundings (⟶ Nuclear Technology – Moderation of Neutrons). The neutron is now said to be thermalized.

1.5.6. *Interaction between Neutrinos and Matter*

In contrast to neutrons, neutrinos are abundant in natural terrestrial radioactivity; more precisely, antineutrinos produced in β^- decay are "naturally" abundant.

Neutrinos are thought to have no rest mass—at least experimental results up to the present show that their rest mass, if any, is vanishingly small. They do not take part in either the electromagnetic or the strong interaction, but only in the weak interaction. Thus a neutrino has a high probability of traveling all the way through the Earth without interacting. The interaction probability of neutrinos with detectors is correspondingly slight; while they are not uninteresting, they are hard to detect.

[Top of Page]

2. Radioactive Elements

Cornelius Keller

Elements having only radioactive isotopes are treated in this article. Plutonium, Thorium, Uranium, and Transuranium Elements are separate keywords.

In 1993, 109 chemical elements have been identified (Fig. 17). They can be divided into three groups:

1. 81 elements with one or more stable isotopes
2. 10 naturally occurring elements composed solely of radioactive isotopes
3. 18 elements composed of radioactive isotopes that do not occur in nature

Figure 17. Periodic table of elements with characterization of the different types of radioelements

81 elements possess one or more stable isotopes. The heaviest element with one stable isotope is bismuth (Z = 83). Several stable elements contain naturally occurring long-lived radioisotopes, usually in low concentrations, for example, ^{40}K with $t_{1/2}$ = 1.28×10^9 a and 0.0117 % abundance. However, in the case of the elements indium and rhenium, the most abundant isotopes are radioactive: ^{115}In ($t_{1/2}$ = 8×10^{14} a, 95.7 % abundance), ^{187}Re ($t_{1/2}$ = 5×10^{10} a, 62.6 % abundance).

10 elements occur naturally but are composed only of radioactive isotopes. Besides the primordial elements uranium and thorium with their longest-lived isotopes ^{238}U ($t_{1/2}$ = 4.486× 10^9 a) and ^{232}Th ($t_{1/2}$ = 1.405×10^{10} a), this group comprises the heavy elements protactinium, actinium, radium, francium, radon, astatine, and polonium. Although most of them are only composed of short-lived isotopes, they are found in nature as the decay products of the primordial long-lived radionuclides ^{238}U, ^{235}U, and ^{232}Th. The naturally occurring isotopes are summa-rized in Figure 18 which also shows their formation and decay properties.

Figure 18. Natural radioactive families

[a] Since the mass numbers within a series can only change by 0 or 4, the parent element and the decay products of the three series must have the atomic masses 4*n*+0, 4*n*+2, and 4*n*+3, where *n* is an integer (the series 4*n*+1 no longer occurs in nature). [b] M=min. [c] UX_2, 1.2 min, β^- 99.85 %, IT γ 0.15 % (IT=isomeric transition). [d] UZ 6.7 h, β^-.

Assuming that the Earth's outer crust (ca. 20 km in depth) contains 4×10^{12} t uranium and about five times the amount of thorium, the following quantities of the longest-lived isotopes of these elements formed by uranium and thorium decay can be calculated.

Polonium	(^{210}Po)	3.3×10^{9} g
Astatine	(^{218}At)	0.1 g
Radon	(^{222}Rn)	9.2×10^{7} g
Francium	(^{233}Fr)	2.1×10^{2} g
Radium	(^{226}Ra)	1.4×10^{13} g
Actinium	(^{227}Ac)	9.1×10^{9} g
Protactinium	(^{231}Pa)	1.4×10^{13} g

The amount of shorter-lived isotopes such as ^{228}Ac, ^{224}Ra, ^{220}Rn, or ^{218}Po is considerably lower.

Because primordial plutonium (^{244}Pu) was detected as early as 1970 and since ^{239}Pu is constantly being produced in uranium deposits via *neutron capture* of ^{238}U, as in nuclear reactors, (^{239}Pu : ^{238}U $\approx 10^{-10} - 10^{-12}$), plutonium can be considered as a naturally occurring element.

*18 elements*have only radioactive isotopes and do not occur in nature. Besides the lighter radioelements technetium (Z = 43) and promethium (Z = 61), this group comprises the transuranium element neptunium (Z = 93) and all elements from Z = 95 (Am) to Z = 109 (Mt = meitnerium).

The elements up to Z = 100 (fermium; longest-lived isotope ^{257}Fm, $t_{1/2}$ = 100 d) are obtained via neutron capture in a nuclear reactor. They can be produced in amounts ranging from kilogram quantities (e.g., neptunium and americium, and also the fission products technetium and promethium) to gram and microgram amounts (e.g., berkelium and californium) down to nanogram quantities (^{257}Fm, the heaviest isotope obtainable via neutron capture).

All isotopes of elements Z > 100 must be produced by *accelerator-based* nuclear reactions with charged particles. Except for rare exotic nuclei (with even shorter half-lifes), they have short half-lifes of $t_{1/2}$ < 1 h. They can be obtained only in tracer quantities (e.g., 10^3 to 10^5 atoms for Z = 101 to Z = 103) or even in form of single atoms for elements $Z \geq 106$.

Superheavy elements — elements with atomic numbers close to the next closed proton shell with Z = 114 — could not yet be identified either in nature or by nuclear reactions, even if some of them may have relatively long half-lifes.

There are few institutions which are able to work with these highly radioactive substances. As a result, the number of publications of general interest, especially review articles, are very scarce; sometimes these articles are published in journals and reports that are not easily available.

Therefore, the interested reader is advised to consult the Gmelin Handbooks of these elements which were published in the 1970s and 1980s. They contain all information in a critically revised form because all chapters were written by experts from all over the world.

Due to decreasing interest in these rare and difficult-to-handle radioelements, no more investigations of special importance — except of ^{99m}Tc for nuclear medicine — have been done in the last decade and, therefore, no review papers have been published recently.

2.1. Promethium

Promethium (Z = 61) was discovered after 1945 as a product of ^{235}U fission by neutrons (J. A. MARINSKY, L. E. GLENDENIN, C. D. CORYELL). The isotopes ^{130}Pm to ^{158}Pm are known, but only β^--active ^{147}Pm [14380-75-7] ($t_{1/2}$ = 2.62 a) has found some industrial importance. ^{145}Pm [15706-44-2] ($t_{1/2}$ = 17.7 a) is the longest-lived promethium isotope but it can only be produced by nuclear reactions involving accelerators and is, therefore, only available in tracer quantities.

^{147}Pm is obtained from high active waste solutions of the PUREX process, together with other fission lanthanides. The waste solution is stored for at least several years and then extracted by a solution of di-(2-ethylhexyl)phosphoric acid in kerosene. Pure ^{147}Pm is subsequently separated by adsorption to a cation exchanger followed by elution with solutions of complexing agents such as nitrilotriacetic acid or ethylene diaminotetraacetic acid.

In its chemical and physical behavior, promethium (electronic configuration [Xe]4 $f^{14}6s^2 6p$) is a typical trivalent rare earth element.

Promethium crystallizes in the double-hexagonal close-packed (dhcp) structure (a = 365 pm, c = 1165 pm) and has a melting point of 1168 °C. It is produced either by reduction of PmF_3 using calcium as a reductant

$$2\,PmF_3 + 3\,Ca \rightarrow 2\,Pm + 3\,CaF_2$$

or in purer form by reduction of Pm_2O_3 with metallic thorium and subsequent sublimation and condensation.

$$2\,Pm_2O_3 + 3\,Th \xrightarrow[10^{-4}\,Pa]{1600\,°C} 4\,Pm\uparrow + 3\,ThO_2$$

Uses. All uses of ^{147}Pm are based on its inherent radioactivity. The heat released on ^{147}Pm decay (0.3 W/g ^{147}Pm) can be transformed into electric energy in isotope batteries via the thermoelectric effect. Backscattering of the electrons emitted by ^{147}Pm is applied for determination of the thickness of material that is composed of elements with low Z, for example a plastic cover on a metallic substrate.

Intimate mixtures of $^{147}Pm_2O_3$ and phosphors such as ZnS(Cu) are widely applied as luminescence materials for watches and space modules.

Handling. ^{147}Pm is a soft β emitter ($E\,\beta_{(max)}$ = 225 keV) so no special radiation shielding measures are necessary. However, when handling solid compounds in powder form tight glove boxes must be used to avoid contamination.

2.2. Technetium

Technetium (Tc, Z = 43), the lightest radioelement was discovered by C. PERRIER and E. SEGRÈ in 1937 after irradiation of molybdenum with deuterons at the Berkeley cyclotron (United States). SEGRÈ took the irradiated sample to Palermo (Italy) where he and PERRIER probably separated the isotope ^{97m}Tc ($t_{1/2}$ = 90 d).

In 1992, all isotopes between mass numbers M = 89 [prepared by the reaction ^{60}Ni(^{32}S, p2n), with $t_{1/2}$ = 12.8 s] and M = 111 (prepared by fission of ^{238}U after bombardment with 20 MeV protons, $t_{1/2}$ = 0.30 s) were identified. ^{98}Tc [32025-58-4] ($t_{1/2} = 4.2\times10^6$ a) is the longest-lived isotope but it cannot be obtained in weighable amounts. The isotope ^{99}Tc [14133-76-7] ($t_{1/2} = 2.14\times10^5$ a) is used for chemical and physical studies of technetium and obtained by fission of ^{235}U with thermal neutrons in ca. 6 % yield. This corresponds to formation of 2.8 g technetium per day and 100 MW_{th} power of a nuclear reactor (i.e., about 30 kg/a in a modern 1300 MW_{el} nuclear power reactor). ^{99}Tc can be recovered from high active waste solutions after reprocessing of spent fuel by the PUREX process.

The most important technetium isotope, however, is ^{99m}Tc ($t_{1/2}$ = 6.0 h) which is the most frequently used radionuclide in nuclear medicine. Due to its short half-life, it must be separated from its mother nuclide ^{99}Mo ($t_{1/2}$ = 66 h) by the use of a generator at the place of application.

Several types of ^{99}Mo/^{99m}Tc generators exist which can supply sterile ^{99m}Tc in high purity and good yield, e.g., by elution of technetium with NaCl solution from an alumina column loaded with ^{99}Mo (Fig. 19).

Figure 19. ^{99m}Tc generator "Tecegen" (Hoechst)

a) Eluate shielding (lead glass); b) Evacuated eluate bottle, 13 mL, 5mL calibration; c) Canula for eluate; d) Adapter for eluate (plastic); e) Transport shielding; f) Transport box; g) Canula for elution solution; h) Box containing elution solution in plastic container; i) Additional shielding; j) Generator column for fission Mo

^{99}Mo [14119-15-4] itself can be produced by two processes (see Section Radionuclide Production from Reactors):

1. Irradiation of ^{98}Mo-enriched molybdenum in a nuclear reactor via neutron capture ^{98}Mo(n, γ)^{99}Mo
2. Irradiation of highly ^{235}U-enriched (≥ 20 %) uranium in a nuclear reactor and separation of the fission product ^{99}Mo (fission yield ≈ 6 %)

The second type of production is preferred because it yields ^{99}Mo with a high specific activity so that the eluted ^{99m}Tc is obtained in high concentration. In contrast, the product of ^{98}Mo irradiation only delivers ^{99}Mo with a much lower specific activity and, therefore, requires larger generators.

Nowadays, an adequate supply of ^{99m}Tc is provided by the so-called ^{99m}Tc generators. These generators are efficient and reliable and differ principally from common generators in the technique of separating technetium from molybdenum. Preferred separation methods are the adsorption of $^{99}MoO_4^{2-}$ onto a solid medium and elution of $^{99m}TcO_4^-$ with saline solution, selective extraction of $^{99m}TcO_4^-$ into organic solvents, and sublimation of ditechnetium heptaoxide at high temperatures.

Technetium has the ground state electronic configuration of [Kr]4*d* ^{6} 5*s*. Its chemical properties are more similar to rhenium than to manganese. Valency states between – 1 and +7 are known, the most stable ones being Tc(IV) and Tc (VII). The most important redox potentials in acidic solution at 298.2 K are:

Metallic technetium can be easily prepared either by reduction of NH_4TcO_4 or TcO_2 with hydrogen at 700 – 900 °C or by electrodeposition from a 1 M solution of NH_4TcO_4 in sulfuric acid. Its most important *physical properties* are:

mp	2250 ± 50 °C
Density	11.47 g/cm^3
Crystal structure	hexagonal close-packed
Lattice dimensions (25 °C)	*a* = 274.07 pm
	c = 439.80 pm
Critical temperature (superconducting)	7.73 ± 0.02 K
Debye temperature	454 K
Standard entropy of formation	31 ± 0.8 J mol^{-1} K^{-1}
Magnetic susceptibility (25 °C)	270×10^{-6}
Specific heat C_p (1000 K)	0.29 J g^{-1} K^{-1}

Chemical Properties. Solid technetium is resistant to oxidation, but in sponge or powder form it is readily oxidized to the volatile heptaoxide when heated in air. The metal dissolves in dilute or concentrated nitric acid, concentrated sulfuric acid, and bromine water, but not in hydrochloric acid. Technetium also dissolves in aqueous acid hydrogen peroxide solutions. It is oxidized by these solvents to pertechnetate, but in the case of bromine water $[TcBr_6]^{2-}$ is also formed.

TcO_2 reacts with fluorine to yield TcO_3F. Contrary to rhenium, no heptafluoride of technetium is known. Only TcF_5 and TcF_6 are obtained, for example, by fluorination of technetium metal at 400 °C. The corresponding reaction with chlorine or bromine at 550 °C produces the tetrahalides $TcCl_4$ and $TcBr_4$. These halides can form hexahalide complexes with an octahedral $TcCl_6^{2-}$ arrangement that are more stable than the corresponding tetrahalides, for example K_2TcCl_6. $TcOCl_4$ and TcO_3Cl are formed if technetium reacts with chlorine that contains oxygen. Sulfur reacts with technetium at elevated temperature to give the disulfide, and carbon to give TcC. A technetium hydride of the composition $TcH_{0.73}$ is formed at 300 °C under a hydrogen pressure of ca. 0.2 GPa.

Only a few compounds have been prepared so far, with Tc in low oxidation states, including:

Tc(–1) $HTc(CO)_5$

Tc(0) $Tc_2(CO)_{10}$, $CoTc(CO)_9$

Tc(+1) $K_5Tc(CN)_6$, $(C_6H_5)_2TcH$, $Tc(CO)_5Cl$

Tc(+2) $[(C_5H_5)_2Tc]_2$

Tc(+3) [Tc(*o*-phenylene-bis-dimethylarsine)$_2Cl_2$]Cl

Tc(+4) TcO_2, M_2TcX_6 (X = F, Cl, Br, I, SCN)

Oxidation of technetium metal by oxygen at 500 °C yields pale yellow Tc_2O_7 (*mp* 119.5 °C, *bp* 310.6 °C) which reacts with

water vapor to form dark red $HTcO_4$. Many pertechnetates such as $LiTcO_4$ or the sparingly soluble $CsTcO_4$ have been prepared and characterized.

Reduction of Tc(VII) solutions or thermal decomposition of NH_4TcO_4 at 450 °C in vacuum gives TcO_2 which has a distorted rutile structure. Brown-black Tc_2S_7 is precipitated from TcO_4^- solution by gaseous H_2S.

Uses. Technetium itself and some of its compounds and ions have properties that should make them suitable for broad industrial applications. However, their inherent radioactivity prevents their general use except in special applications, for example, ^{99m}Tc in nuclear medicine.

Metallic technetium supported on Al_2O_3 or SiO_2 is an excellent catalyst for hydrogenation, dehydrogenation, dehydrocyclization, and cracking reactions, particularly of C_6 and C_7 species. The reforming of naphtha to gasoline with higher aromatic content is catalyzed by technetium-promoted Cr_2O_3 catalysts, at a lower reaction temperature than other promoted catalysts. Technetium can, therefore, partly substitute for expensive platinum catalysts, especially as technetium catalysts are highly resistant to sulfur poisoning.

Metallic technetium is a weak-coupling type II superconductor with a high critical temperature (T_c = 7.73 K). Some technetium alloys have still higher critical temperatures up to $T_c \approx 15.0$ K for a technetium – molybdenum alloy with 60 atom % technetium.

TcO_4^- ions are excellent corrosion inhibitors even in the presence of corrosive media and at temperatures ≤ 250 °C. At pH ≈ 6 and 10 ppm Cl^-, a solution of 50 ppm technetium (≈ $5 \cdot 10^{-4}$ M Tc) suppresses corrosion of a 0.1 % carbon steel even after 20 years. The corrosion rate is at least four orders of magnitude less than in the absence of TcO_4^- ions. The surface concentration of technetium on the steel corresponds to about a tenth of a monolayer. Furthermore, technetium-coated stainless steel does not corrode in seawater.

^{99}Tc is used very often as a standard source of β radiation for radiometry and dosimetry. Such sources are safe and convenient to handle because of the lack of γ radiation.

In nuclear medicine, chemical compounds of ^{99m}Tc are widely used for radionuclidic imaging of the brain, liver, lung, and skeleton, and to a lesser extent in thyroid scintigraphy. ^{99m}Tc-labeled radiopharmaceuticals have been developed that are suitable for both static and dynamic evaluation of renal and cardiac pathology (see Chap. Production of Artificial Radionuclides). Sales of ^{99m}Tc-labeled products account for about 75 % of the total sale of radiopharmaceuticals in the United States; similar trends are observed in Europe.

Handling. ^{99}Tc is a soft β emitter so no special radiation protection measures are necessary. Tight glove boxes must be used to avoid contamination of work places and incorporation when handling powdered samples of ^{99}Tc compounds. Lead shielding is necessary for $^{99}Mo/Tc$ generators because ^{99}Mo also emits γ-rays.

2.3. Polonium

Element 84 was discovered in 1894 by P. and M. CURIE. Its discovery was possible because of its inherent radioactivity.

In 1993 all isotopes between mass numbers M = 193 and M = 218 are known including many relatively long-lived isomers. The longest-lived isotope ^{209}Po [15735-81-6] ($t_{1/2}$ = 102 a) is only available through charged-particle nuclear reactions and therefore not produced in weighable amounts. Nearly all the chemical and physical studies on polonium were performed with the pure α emitter ^{210}Po ($t_{1/2}$ = 138 d).

Even though polonium was first discovered by the separation of ^{210}Po from uranium ores, due to the very small amount of ^{210}Po (equilibrium concentration 7.4×10^{-11} g ^{210}Po/g ^{238}U) in ores, nowadays most ^{210}Po is isolated in a different way. It is either separated from "old" radium samples or more recently by irradiation of very pure bismuth with neutrons in a nuclear reactor, even if the neutron capture cross section σ is low:

One year of irradiation of 1 kg bismuth at a neutron flux of 10^{14} n cm^{-2} s^{-1} gives 25 mg ^{210}Po (ca. 4×10^{12} Bq). The isolation of such quantities from natural sources is practically impossible. Following irradiation of bismuth, ^{210}Po is separated from molten bismuth by vacuum distillation. Final purification of polonium generally is accomplished by its spontaneous deposition on silver or copper powders. *Metallic polonium* is then easily prepared by sublimation of this deposit at about 700 °C. It is also obtained by reduction of polonium sulfide with hydrogen at 500 °C. Polonium sulfide itself is precipitated from an acid solution of polonium ion by gaseous H_2S.

Polonium with electronic configuration [Xe]4 $f^{14}5d^{10}6s^2 6p^4$ is the heavy homologue to tellurium. The oxidation states – 2, +2, +4, and +6 are known, but Po(IV) (ionic radius 102 pm) is the most stable one. Po(VI) (ionic radius 67 pm) is easily reduced to a lower oxidation state by its own radiation.

Important *physical properties* of polonium metal are:

mp	≈ 250 °C
bp	962 °C
Atomic radius	164 pm
Vapor pressure	
(438 – 745 °C)	
log (*p*/Pa) =	(964.36 ± 0.9064) – (716860 ± 893)/ *T* (°C)
Structure	
α Po (<18 °C)	cubic, *a* = 335.9 pm
β Po (>54 °C)	rhombohedral, *a* = 336.9 pm, α = 98.23°
Density	
αPo	9.142 g/cm^3
β Po	9.352 g/cm^3

Chemical Properties. Polonium is soluble in HCl and forms Po(II), in HNO_3 and aqua regia Po(IV) is produced.

Po(VI) solutions are obtained by the oxidation of Po(IV) with Cl_2, $K_2Cr_2O_7$, or Ce(IV) – HNO_3. SO_2 and N_2H_4 reduce Po (IV) to Po(II), by reduction with $SnCl_2$, Ti(III), and $NaHSO_3$, a precipitate of finely divided metallic polonium is formed.

Compounds. Polonides of several metals with the composition MPo (e.g., M = Mg, Mn, Y, rare earth element) are prepared by the interaction of polonium vapor with powdered metals. Most of these polonides dissociate at ca. 700 °C, only rare earth polonides are stable up to 1000 °C.

Polonium monoxide, PoO [19268-61-2], is obtained by thermal decomposition of polonium selenide. The more stable PoO_2 [7446-06-2], is formed by thermal decomposition of, for example, $PoO(OH)_2$ or Po(IV) nitrate, or by reaction of metallic polonium and oxygen. It can be sublimed in an oxygen stream at 885 °C but decomposes in vacuum at 500 °C. PoO_2 vapor reacts with rare earth oxides to form compounds such as $Pr_2O_3 \cdot PoO_2$ and $Dy_2O_3 \cdot PoO_2$.

Halides such as $PoCl_4$ [10026-02-5] and $PoBr_4$ [60996-98-7] are formed when polonium metal reacts with chlorine or bromine at ca. 100 °C. At 200 °C these halides decompose to the corresponding polonium dihalides. Complex halides such as $M_2^{I}PoX_6$ (M = K, Rb, Cs; X = Cl, Br, I) of Po(IV) and $MPoCl_3$ and M_2PoCl_4 of Po(II) are also known.

Due to the high radioactivity of ^{210}Po, relatively unstable compounds such as PoH_2, PoF_6, PoO_3, and organometallic compounds could be identified only in tracer amounts but not in quantities that are needed for detailed investigations of their properties.

In aqueous solution, polonium ions are easily hydrolyzed even at pH ≈ 1, if not complexed by, for example, oxalic, citric, or tartaric acids. Po(IV) in particular, is readily extracted from aqueous solutions by, e.g., tri-*n*-butyl phosphate, dithizone – $CHCl_3$, and amines. Polonium is adsorbed as complex ions by anion exchangers in strong acid solution — elution must be performed rapidly due to the fast decomposition of the ion exchanger by α activity.

Uses. ^{210}Po is the only isotope that finds broad application. It is used as an energy source for radioisotope batteries. This isotope has the advantage that it does not emit γ-rays therefore heavy weight shielding of the batteries can be avoided. The disadvantage is the short half-life of ^{210}Po. ^{210}Po (140 W_{th}/g) was especially used as an energy source in Soviet space missions, e.g., in Lunochod-1 and Lunochod-2. About 10^{15} Bq ^{210}Po are needed for a radioisotope battery that delivers 1 kW electric power. The polonium is mostly provided in the form of rare earth polonides.

^{210}Po is used also as an α emitter for (α, n) neutron sources. A BeO – ^{210}Po source emits up to 93 neutrons per 10^6 α particles.

Handling. Tracer amounts of ^{210}Po can be handled in well-working fume hoods but even microgram quantities of ^{210}Po require handling in tight glove boxes due to unavoidable α recoil and the consequent contamination of the working area.

2.4. Astatine

Astatine, the heaviest halogen element (Z = 85) was discovered in 1940 by D. R. CORSON, K. R. MCKENZIE, and E. SEGRÈ as a product of bombardment of bismuth by 20 MeV α particles via the reaction ^{209}Bi (α, 2n)^{211}At. Minute amounts of short-lived ^{215}At, ^{218}At, and ^{219}At are intermediates in the natural ^{235}U- and ^{238}U-decay chains.

All astatine isotopes of mass numbers between M = 196 and M = 223 have been identified. Only the easily obtainable isotopes ^{209}At [5755-38-1] ($t_{1/2}$ = 5.5 h), ^{210}At [18830-37-0] ($t_{1/2}$ = 8.1 h), and ^{211}At [15755-39-2] ($t_{1/2}$ = 7.2 h) are of importance, especially for use as radiopharmaceuticals in nuclear medicine. Irradiation of *bismuth* with a l-μA beam of 43 MeV α particles for 1 h yields ca. 1.5×10^9 Bq ^{210}At plus 1.1×10^9 Bq ^{211}At, corresponding to ca. 2 ng of the element. To separate the produced astatine, the irradiated bismuth is heated to 660 °C at 0.1 Pa. The volatilized astatine can be condensed in a trap cooled by liquid nitrogen. A mixture of all three longer-lived astatine isotopes is formed by spallation reactions when *thorium metal* is bombarded with 600 MeV protons. This method gives higher yields of astatine [2×10^7 Bq At μA^{-1} h^{-1} $g(Th)^{-1}$] and is used as a routine procedure at Dubna in the CIS.

Because of its high specific activity, astatine (electronic configuration [Xe]$4f^{14}5d^{10}6s^2 6p^5$) can only be handled in tracer quantities. Properties of the element (such as *mp* 244 °C and *bp* 309 °C) are only estimated figures.

Chemical Properties. Tracer studies have given, however, a good indication of the properties of the elements and its ions, especially in solution. Astatine occurs in oxidation states –1, 0, +1, +3, +5, and +7 and it has also been shown that astatine is more electropositive than iodine [redox potentials X^-/X_2(aq) are 0.62 V for iodine and 0.3 V for astatine]. The molecule At_2 has never been observed, however, because the concentration and thus chance of impurities to react with an astatine atom is generally much higher than the concentration of astatine itself.

Therefore, At(0) was only identified in the form of AtI. It is easily adsorbed by metal surfaces and extracted from aqueous solutions by, for example, benzene or CCl_4. Strong reducing agents form At^-, oxidation by $K_2Cr_2O_7$, for example, yields At^+ in the form of its aquo complex. At(V) is formed by oxidation of lower valency states of astatine by $(NH_4)_2S_2O_8$ or IO_3^-/IO_4^-, At(VII) by oxidation with YeF_2 in warm alkaline solution.

Organometallic compounds such as C_2H_5At or C_6H_5At were synthesized in tracer quantities by using iodine as nonisotopic carrier as well as, for example, astatine acetic acid ($AtCH_2COOH$) or astatine-labeled radiopharmaceuticals (γ-globulin, albumin, etc.). In most cases isotope exchange reactions with corresponding iodine compounds are used for their synthesis.

Uses. Astatine-labeled organic compounds have high potential as radiopharmaceuticals, both for diagnostics and therapy. These compounds can be, for example fixed onto antibodies for immunodiagnostic studies. It is very important, however, to synthesize compounds with a strong fixation of astatine. Otherwise free astatine in ionic form is accumulated in the thyroid similar to iodine and colloidal astatine is accumulated in the liver, resulting in unwanted radiation exposure to these organs.

Handling. In tracer amounts, astatine can be handled safely in well-aerated fume hoods; incorporation of astatine has to be strictly avoided.

2.5. Radon

Radon, the heaviest noble gas, was discovered in 1900 as a decay product of radium by F. E. DORN.

Radon isotopes with atomic masses between 199 and 226 are known, of which ^{222}Rn [14859-67-7] ($t_{1/2}$ = 3.82 d), ^{220}Rn [22481-48-7] ($t_{1/2}$ = 55.6 s), and ^{219}Rn [14835-02-0] ($t_{1/2}$ = 3.96 s) are members of natural decay series. On average, they contribute to about half of the natural radiation dose the population is exposed to.

Despite the fact that the chemical behavior of radon is only known from tracer experiments with the longest-lived ^{222}Rn, there is no doubt that radon is the most reactive noble gas. Reaction of radon with fluorine or halogen fluorides, such as BrF_3, is likely to produce RnF_2 which can be reduced to radon by hydrogen only at temperatures > 500 °C. Radon fluoride can be sublimed at about 250 °C. It also seems to be possible to oxidize radon with O_3.

There are no known uses of radon, except application of ^{222}Rn capsules for the treatment of cancer. The release of radon from solid substances (“emanation method” by O. HAHN) is often used to study structural changes of solids.

SbF_5 in the presence of ClF_3 and $N_2F_2Sb_2F_{11}$ might be suitable for the removal of radon from the air in uranium mines in order to reduce radiation dose to workers by the formation of RnF.

2.6. Francium

Element 87 is the most unstable of all naturally occurring elements. It was discovered in 1939 by M. PEREY. ^{223}Fr [51712-59-5] ($t_{1/2}$ = 21.8 min) is the most stable of all 27 isotopes.

Relatively pure ^{223}Fr solutions are obtained by its elution with NH_4Cl – CrO_3 from a cation exchanger loaded with ^{227}Ac. The solution is further purified by passing it through a SiO_2 column loaded with $BaSO_4$.

Francium is only monovalent and shows a very similar behavior to the other heavy alkali elements. Francium has the most negative standard potential of all elements.

No industrial applications or uses in nuclear medicine have yet been found.

2.7. Radium

Radium (Z = 88) was discovered in 1898 by P. and M. CURIE and G. BÉMONT. ^{226}Ra [13982-63-3] ($t_{1/2}$ = 1600 a) is the longest-lived of all the 25 radium isotopes known to date. Its concentration in uranium ores is 0.36 µg per gram uranium. ^{223}Ra [15623-45-7], ^{224}Ra [13233-32-4], and ^{228}Ra [15262-20-1] also occur in nature.

According to its electronic configuration [Rn]$7s^2$, radium shows the typical behavior of an alkaline earth element with a large ionic radius. It is obtained from uranium ores by a mixed precipitation – ion exchange procedure.

Radium metal is prepared by reduction of the oxide by aluminum at 1200 °C in vacuum. The pure metal has a cubic body-centered structure (a = 515 pm) such as barium and a *mp* of 700 °C. The known compounds, including the halides RaX_2 (X = F, Cl, Br, I), the oxide RaO, the carbonate $RaCO_3$, and the ternary oxides $RaCeO_3$ and $RaMO_4$ (M = Cr, Mo, W) are isostructural with corresponding barium compounds. Because of its large ionic radius, radium forms weak complexes and is not well extracted from aqueous solutions except at high pH values.

Uses. The use of ^{226}Ra as a γ emitter in nuclear medicine for cancer therapy lost its importance when larger and cheaper ^{60}Co sources became available. Also most (α, n)-neutron sources based on ^{226}Ra were replaced by ^{241}Am – Be sources even if the number of emitted neutrons in ^{226}Ra sources are higher (for $RaBeF_4$: 1.84×10^6 neutrons per second and per gram ^{226}Ra).

Radium is mainly used to prepare ^{227}Ac via neutron capture in a nuclear reactor.

Handling. ^{226}Ra requires special precautions to work with because it is considered the most toxic radioelement. Handling of ^{226}Ra is possible only in tight glove boxes where the circulating air stream must also be treated to avoid the escape of decay product ^{222}Rn to the environment. Special care must be taken when opening disused radium ampoules because of possible overpressure formed by the decomposition of water.

2.8. Actinium

The element with Z = 89 was discovered in 1899 by A. DEBIERNE, but F. O. GIESEL in 1902 was the first to have prepared pure actinium. Of all 25 known isotopes, only the longest-lived ^{227}Ac [51712-63-1] ($t_{1/2}$ = 21.77 a) has some importance. In uranium ores its amount is too low to be recovered (2×10^{-10} g per gram uranium), so nearly all ^{227}Ac is obtained by irradiation of ^{226}Ra. Three months irradiation at a neutron flux of 5×10^{14} n cm^{-2} s^{-1} transforms 2 % of ^{226}Ra to ^{227}Ac. In the 1970s, about 18 g $^{227}Ac_2O_3$ were prepared by this method. The ^{227}Ac obtained was separated from ^{226}Ra and decay products by a precipitation – ion exchange process.

Because of its electronic configuration [Rn]$6d\,7s^2$ and ionic radius (r = 111 pm for Ac^{3+}), actinium closely resembles lanthanum, but only few compounds [e.g., the oxide Ac_2O_3, the sulfide Ac_2S_3, the phosphate $AcPO_4 \cdot 0.5\,H_2O$, the halides AcX_3, and oxide halides AcOX (X = F, Cl, Br, I)] have been synthesized up to now.

Actinium metal is obtained by reduction of Ac_2O_3 with thorium at 1750 °C and 10^{-4} Pa. It crystallizes in the cubic β-lanthanum type structure with a lattice constant of a = 531.5 pm. In solution only Ac^{3+} occurs. The stability of Ac^{3+} complexes is low due to the large ionic radius. Because of this, actinium can only be extracted from aqueous solutions at relatively high pH values with low distribution coefficients. Most solution experiments were performed by using ^{228}Ac ($t_{1/2}$ = 6.13 h), separated from ^{228}Ra ($t_{1/2}$ = 5.7 a).

Uses. ^{227}Ac is a radionuclide with high specific power (14.3 W_{th}/g) and besides ^{244}Cm, is the only radioisotope used for thermionic transformation of the heat of decay into electricity. For a thermionic battery that transforms 12 % of heat into electricity, about 17 g $^{227}Ac_2O_3$ (equivalent to about 5×10^{13} Bq) are needed to obtain 250 W_{th}. Due to the instability of thermionic batteries compared to thermoelectric devices, the interest in ^{227}Ac is currently decreasing.

Handling. Handling of ^{227}Ac is possible only in tight glove boxes, gram-amounts require hot cells with γ shielding. Well-aerated fume hoods are sufficient for the handling of trace quantities of all actinium isotopes.

2.9. Protactinium

The element with Z = 91 was discovered in 1913. K. FAJANS and O. GÖHRING were probably the first to have separated pure protactinium.

^{231}Pa [14331-85-2] ($t_{1/2}$ = 32 480 a) is the most important of all 24 known isotopes, even though ^{233}Pa [13981-14-1] is of special importance because it is formed as an intermediate in the production of fissile ^{233}U from nonfissile ^{232}Th by

neutron capture

$$^{232}\mathrm{Th}(n,\gamma)\,^{233}\mathrm{Th}\xrightarrow[22.3\ \mathrm{min}]{\beta^-}\,^{233}\mathrm{Pa}\xrightarrow[27.0\ \mathrm{d}]{\beta^-}\,^{233}\mathrm{U}$$

$$\sigma = 7.4\ \mathrm{barn}$$

This process is used in thorium high temperature reactors (THTR, see ⟶ Nuclear Technology) which utilize the fivefold occurrence of thorium in nature compared to uranium.

The separation of ^{231}Pa from residues of uranium production is a difficult process. Nevertheless, around 1960 ca. 100 g pure $^{231}Pa_2O_5$ were isolated from residues of the uranium production at Springfield, United Kingdom, that contained 3.7 ppm ^{231}Pa. In future, larger quantities of ^{231}Pa might be recovered from nuclear waste originating from reprocessing of thorium fuels, because it is formed via

$$^{232}\mathrm{Th}(n,2n)\,^{231}\mathrm{Th}\xrightarrow[25.6\ \mathrm{h}]{\beta^-}\,^{231}\mathrm{Pa}$$

by the fast neutrons in a THTR nuclear reactor.

With its electronic configuration [Rn]$5f^2 6d^1 7s^2$, protactinium is the first element to posses 5 *f* electrons in the ground state. Both in the solid state and in solution protactinium can occur in the oxidation state Pa^{4+} (r = 96 pm) and Pa^{5+} (r = 90 pm). In its chemical and physical behavior protactinium is much more similar to tantalum than to typical 5 *f* elements.

Protactinium metal is best prepared by the Van Arkel method using a PaC – I_2 mixture (⟶ Hafnium and Hafnium Compounds – Refining). α Protactinium is tetragonal-body centered (a = 393.1 pm, c = 323.6 pm), β protactinium is cubic face-centered (a = 501.9 pm). The melting point of protactinium is 1572 ± 20 °C.

Compounds. The solid state chemistry of protactinium is quite well known. Binary compounds exist such as the tetrahalides PaX_4 and pentahalides PaX_5 and complex compounds including the sparingly soluble K_2PaF_7. The very stable white Pa_2O_5 occurs in at least five modifications. The reduction of Pa_2O_5 with pure hydrogen at 1550 °C yields black PaO_2. A protactinium peroxide of still unknown composition can be precipitated from diluted acids. This method is used to separate protactinium from tantalum and niobium which form soluble peroxide complexes.

Pa(V) is hydrolyzed in aqueous solution even in strong acids, if not complexed, for example, by F^- ions. No Pa^{5+} exists in solution; only partly hydrolyzed species with two positive charges (in ca. 1 M HCl) or one positive charge (in 10^{-3} – 10^{-1} M H^+) could be identified. Pa(V) is readily adsorbed onto precipitates, surfaces (even metal surfaces), graphite, quartz, etc. The partly hydrolyzed protactinium species form very stable complexes with most organic ligands. Pa(V) can be extracted from aqueous solution by amines and most neutral and acid phosphoric and phosphonic extraction agents. The distribution coefficients are high.

Pa(IV) solution is obtained by reduction of Pa(V) solutions using chemical (e.g., zinc) or electrochemical methods. The behavior of Pa(IV) is very similar to all other actinides of oxidation state IV, however, its tendency to hydrolyse is much higher.

Due to the unavoidable hydrolysis and formation of radiocolloids, solutions of protactinium in various oxidation states must be freshly prepared before use. The large number of unexplainable results found in the literature are mostly due to using degraded protactinium solutions with partly hydrolyzed, nonspecified protactinium species that change composition by time, even in 6 M HCl.

Uses. Protactinium plays an important role in the THTR fuel cycle, especially because of the high neutron absorption cross section of ^{233}Pa ($t_{1/2}$ = 27.0 d) that lowers the amount of fissile ^{233}U formed. Therefore, several processes, for example, for a “molten salt reactor”, have been developed to separate protactinium continuously during reactor operation with the consequence that ^{233}Pa will decay outside the reactor core and, therefore, not absorb neutrons. However, many technological problems have to be solved before practical application.

Handling. ^{231}Pa must be handled in tight glove boxes, whereas tracer chemistry of protactinium (e.g., with ^{233}Pa) can be performed in well-aerated fume hoods.

3. Production of Artificial Radionuclides

Walter Wolf and Jashovam Shani

Introduction (see Chap. Introduction). Artificial radionuclides can be produced when nuclei of stable elements are modified as a consequence of their interaction with high energy particles. Such particles may be neutral, such as neutrons, or charged, either positively (e.g., protons, deuterons, etc.) or negatively. The stable nuclide that is subject to particle bombardment is called the *target*, and the bombarding particles can arise either as the result of a nuclear decomposition

(such as neutrons in a reactor), or through acceleration of a charged particle to the desired energy level. Theoretically, any elemental particle or nucleus can be accelerated, but radionuclide production for biomedical and chemical purposes (as opposed to the study of nuclear properties) is limited to a finite number of particles and energy ranges.

A nuclear reaction leading to an artificial radionuclide can be formulated as follows:

$$ {}^{M}_{A}\mathrm{T} + {}^{M'}_{A'}\mathrm{P} \longrightarrow {}^{M+M'}_{A+A'}\mathrm{CN} \longrightarrow {}^{M''}_{A''}\mathrm{RN} + {}^{M'''}_{A'''}\mathrm{P}_1 + {}^{M''''}_{A''''}\mathrm{P}_2 \quad (3.1) $$

where T is the target nuclide of atomic number A and mass *M*, and where the bombarding particle P has mass *M′* and atomic number *A ′*. An absorptive collision will result in a nucleus in an activated transition state that is called a compound nucleus (CN) [4], usually so unstable that it will decompose into two or more products: a radionuclide RN of mass *M″* and atomic number *A″*, and one (P_1) or more (P_2, . . .) additional particles that carry the excess mass. Finally, an energy term *Q* is included to complete the balance of Equation (3.1). Its value will be positive if energy is released (an exothermic reaction), and negative if energy must be provided (an endothermic reaction).

The following are examples of some of the more common nuclear reactions used in the production of radionuclides. The first illustrates a neutron activation reaction:

$$ {}^{98}_{42}\mathrm{Mo} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{99}_{42}\mathrm{Mo}^{**} \longrightarrow {}^{99}_{42}\mathrm{Mo} + E(\gamma) \qquad (3.2) $$

where excess energy is released as two primary ϒ quanta of 6.92 and 0.78 MeV. Such a reaction is normally abbreviated in nuclear chemical notation as

$$ {}^{98}\mathrm{Mo}(\mathrm{n},\gamma){}^{99}\mathrm{Mo} \qquad (3.3) $$

where the expression in parentheses indicates first the bombarding particle followed by the emitted particle(s) or photons. When mass particles (P_1, P_2) are emitted, primary photons are usually not listed.

A simple charged particle reaction is illustrated by one of the most common reactions used in the production of ^{18}F:

$$ {}^{18}\mathrm{O}(\mathrm{p},\mathrm{n}){}^{18}\mathrm{F} \qquad (3.4) $$

Because the entering particle — the positively charged proton — must overcome the coulombic barrier of the oxygen nucleus (which has a charge of +8), there is a minimum threshold energy required for the bombarding particle to allow this reaction to occur. While most of the excess energy of the compound nucleus is dissipated by energy carried by the emitted particle and by primary ϒ quanta released in the reaction, significant energy remains as kinetic energy in the radionuclide itself, a feature responsible for the “hot atom” [5] characteristics of most radionuclides produced in situ.

Nuclear reactors are the most common and efficient devices to produce neutrons required in this type of radionuclide production, while charged particles, such as protons or deuterons (i.e., nuclei of ^{1}H or ^{2}H), must be accelerated to provide them with the energy required by the nuclear reaction in question. Devices for this purpose are called charged-particle accelerators. Both sets of systems were initially developed during the 1930s and then adapted to a large scale during World War II as part of the Manhattan Project [6], [7].

Several key features distinguish the production of radionuclides in a reactor from that in charged-particle accelerators: (1) absorption of *neutrons* usually results in a nucleus with an excess of neutrons, which will therefore disintegrate by emission of an electron (β decay). Absorption of a *charged particle* will result in a nucleus that is neutron-deficient, which will decay by either positron (β^+) emission or electron capture (EC); (2) *thermal neutrons* (E_{av} = 0.025 eV) can penetrate into a nucleus, whereas a significant (threshold) energy is required for *charged particles* to overcome the coulombic barrier; (3) a reactor can usually accommodate many targets for simultaneous irradiation, sometimes over weeks or months, whereas a cyclotron or other charged-particle accelerator can usually accommodate only one or, at most, a small number of targets to be irradiated in some interleaved manner, and then, usually, only for a short period of time.

Another important consideration is that the nature of the nuclear reaction (hence, radionuclide production) may be very much a function of the energy of the accelerated particle. As an example, consider two types of interactions of protons with iodine. When the bombarding protons have low energy (5 MeV < E_p< 20 MeV) the excess energy in the nucleus results only in the ejection of one neutron (Eq. 3.5), whereas at much higher bombarding energies (> 60 MeV) the excess energy leads to ejection of several nucleons (5 neutrons in Eq. 3.6):

$$ {}^{127}\mathrm{I}(\mathrm{p},\mathrm{n}){}^{127}\mathrm{Xe}\ 5\ \mathrm{Mev} < E_{\mathrm{P}} < 20\ \mathrm{MeV} \qquad (3.5) $$

$$ {}^{127}\mathrm{I}(\mathrm{p},5\,\mathrm{n}){}^{123}\mathrm{Xe}\ 60\ \mathrm{MeV} < E_{\mathrm{P}} < 80\ \mathrm{MeV} \qquad (3.6) $$

Other reactions may occur in this system at intermediate proton energies (e.g., p, 2n; p, 3n; p, pn). A plot of production yields for various nuclear reactions versus energy of the incident particle is called an excitation function. However, when the energy of the bombarding particle exceeds 100 MeV, then the stability and organization of the compound nucleus is so severely modified that various nuclear fragments are emitted. Such reactions are called *spallation reactions*, and will be discussed in Section Radionuclide Production from Reactors.

Finally, absorption of a neutron by ^{235}U literally represents the drop that spills the glass: the resulting compound nucleus is so unstable that it breaks up into a large number of nuclides and several neutrons, and a considerable amount of energy is

released. This process is known as *nuclear fission* (see also ⟶ Nuclear Technology – Physical Processes), and has been used for the production of a number of radionuclides, including ^{60}Co, ^{90}Sr, ^{99}Mo, and ^{131}I.

Probably the major consideration in choosing a method for the production of a given radionuclide is the expected yield. With Equation (3.7) the yield (in curies) of a given radionuclide can be calculated at the end of neutron bombardment (EOB). Similar equations can be written for radionuclide production in a charged particle accelerator:

$$A = N \cdot \sigma \cdot F \cdot S \tag{3.7}$$

where A is the activity, in curies, at time t; N the number of atoms of target nuclei in the sample; σ the production cross section in cm^2 (1 barn = 10^{-24} cm^2); F the particle flux in neutrons cm^{-2} (n cm^{-2} s^{-1}); S the saturation factor = 1 – exp (– 0.693 · $t/t_{1/2}$); $t_{1/2}$ the physical half-life of the radionuclide produced; and t the time of bombardment or irradiation.

The activity remaining at time d will be $A_d = A_t \cdot D$, where D, the decay factor, is $D = \exp(-0.693 \cdot t/t_{1/2})$.

Several of the factors in the above equation depend on physical properties of the elements, such as the cross section σ and the $t_{1/2}$ of the resulting radionuclide. The higher the cross section σ, the greater the yield. Other parameters in the above equation can be adjusted to the reaction in question and required yield. The number of atoms undergoing transmutation is $N = (6.02\times10^{23} \cdot \text{mass} \cdot \%\text{isotopic abundance})/ A_r$. If the isotopic abundance of the target nuclide is less than 1, then the yield of radionuclide production can be increased by using a target enriched in the desired nuclide. This not only increases the yield of radionuclide production, but may also increase the purity of the desired radionuclide by minimizing the production of unwanted radionuclides. Another parameter that can be adjusted is the flux of neutrons. The higher the flux, the greater the yield. Finally, the time of bombardment is important: the combined rates of formation and decay eventually lead to a steady-state condition. For this reason, many radionuclide production yields are expressed as yields at half-saturation. Similar considerations apply to production in a charged-particle accelerator.

The highest capital investments are associated with the machines that produce the bombarding particles (nuclear reactors or charged particle accelerators). Some of the characteristics of these devices are examined, followed by examples of how a number of key radionuclides have been produced, and how the production of each has been optimized in the system of choice.

3.1. Nuclear Reactors

A reactor intended for radionuclide production is a device that produces neutrons as a consequence of nuclear fission. An average of 2.2 neutrons is produced per fission of a ^{235}U nucleus induced by slow neutrons, and the energies of the generated neutrons range from 14 MeV to a fraction of an electron volt. Operationally, such neutrons are classified as fast (E > 1 MeV), thermal or slow (E_{av} = 0.025 eV), or epithermal (of intermediate energies). Although the various types of neutrons can lead to different radionuclides, there is no way to separate the neutrons, so one must be well aware of the mix available at various positions in each reactor. However, most radionuclide production is achieved using thermal neutrons. Insertion of targets to and their removal from the reactor is accomplished with hydraulic systems (“rabbits”) that enable operators to introduce or withdraw irradiated samples at any time.

Reactors vary in size, according to their neutron flux; the fuel elements used (natural or enriched uranium); and type of cooling system (distilled or heavy water). Some of the smaller reactors, such as the Slowpike reactor manufactured by Atomic Energy of Canada Limited (AECL) or the TRIGA reactors from General Atomics, are of the “swimming-pool” type. They use uranium as fuel enriched to 20 % (uranium – zirconium hydride), and they supply fluxes of 10^{12} n cm^{-2} s^{-1} (during 4 h) or 2×10^{11} n cm^{-2} s^{-1} (during 24 h). Such a *low-flux nuclear reactor* yields relatively small amounts of radionuclides (in the order of a few millicuries), usually with low specific activities (under 100 mCi/mmol). These reactors operate at up to 2 MW power. At the other end of the spectrum are the *high-flux reactors*, which operate at about a 100 MW power level, and have thermal neutron fluxes of 2 – 5×10^{15} n cm^{-2} s^{-1}. There are very few such reactors available for radionuclide production. Most of those commonly used are of the *intermediate type*, with fluxes in the 10^{13} – 10^{14} n cm^{-2} s^{-1} range and operating at 10 – 40 MW power. They are water-moderated and cooled, and use 10 – 93 % enriched ^{235}U – Al or UO_2 pellets as fuel. Any listing of such facilities would very rapidly become outdated given the environmental and political concerns associated with nuclear reactors. Current information is readily available from the IAEA (Vienna, Austria) or from the national authority in any country that regulates the use and possession of radioactive materials.

In a typical reactor, natural uranium enriched with ^{235}U or ^{233}U undergoes fission and produces heat, fission products, and neutrons for maintaining the chain reaction. Because there is no coulombic barrier to neutrons, neutrons of very low kinetic energies can interact with target nuclei and cause nuclear reactions. The most frequent reaction is of the (n, γ) type, which yields “neutron-rich” radionuclides. Two other common nuclear reactions are (n, p) and (n, α), which may be induced by both slow (thermal) and fast neutrons. In the first of these reactions (n, γ), the radionuclide produced is usually identical to the chemical element that has been bombarded. Hence, this process is also called “activation”; one of its limitations is that the specific activity of the resulting radionuclide will be low due to “dilution” with the original isotope. In the latter two reactions, however, the radionuclide that is produced is chemically different from the target element, and a chemical separation can (and must) be carried out [8]. Other common processes involve isolating radionuclides produced during the fission of uranium, or following successive neutron capture and Szilard – Chalmers [5] recoil-enrichment reactions (see Nuclear Reactors).

The materials most commonly used as targets for nuclear reactions are densely-packed solids, such as metal wires, foils, and powders, so that the maximum number of neutrons can be absorbed within the exposed volume. Some chemical

compounds of the metals (e.g., oxides, carbonates, and nitrates) may also be used, but such targets are likely to undergo both Szilard – Chalmers and thermal decompositions during irradiation, thus necessitating more complex purification at the end of bombardment. The most common containers for irradiations are aluminum, quartz, or plastic tubing, as well as aluminum foil packets, which are sealed in an aluminum capsule. The heat generated in exothermic nuclear reactions (n, γ and n, fission) limits the mass of the irradiated target to about 1 g, because the amount of heat absorbed during radiation increases with mass and specific gravity. The (n, γ) reaction usually produces only one radionuclide, so the final step in its production is separation from the container and dissolution or extraction in a suitable solvent. Some of the most common radionuclides produced in nuclear reactors are listed in Table 1.

Table 1. Examples of radionuclides produced in a nuclear reactor (this tabulation is based on a more extensive table in [10])

Radionuclide produced	$t_{1/2}$	Mode of decay	Main γ energies emitted, keV (% abundance)[d]	Selected mode of production
^{18}F	110 min	β^+, EC [a]	511 (194)	^{16}O (^3H, n) [b]
^{32}P	14.3 d	β^-		^{31}P (n, γ)
^{24}Na	14.9 h	β^-	1369 (100); 2754 (100)	^{23}Na (n, γ)
^{35}S	87.9 d	β^-		^{35}Cl (n, p)
^{36}Cl	3.1×10^5 a	β^-		^{35}Cl (n, γ)
^{42}K	12.3 d	β^-	1524 (18)	^{41}K (n, γ)
^{47}Ca	4.5 d	β^-	1308 (74)	^{46}Ca (n, γ)
^{51}Cr	27.8 d	EC	3.2 (9)	^{50}Cr (n, γ)
^{58}Co	71.3 d	β^+	511 (30); 810 (99)	^{58}Ni (n, p)
^{59}Fe	45.6 d	β^-	1095 (56); 1292 (44)	^{58}Fe (n, γ)
^{64}Cu	12.8 h	β^- β^+, EC [a]	511 (38)	^{63}Cu (n, γ)
^{69m}Zn	13.8 h	IT	439 (96)	^{68}Zn (n, γ)
^{85}Kr	10.7 a	β^-	514 (4)	^{235}U (n, fission)
^{85}Sr	64 d	EC [a]	514 (100)	^{84}Sr (n, γ)
^{86}Rb	18.7 d	β^-	1078 (9)	^{85}Rb (n, γ)
^{90}Y	64 h	β^-		^{89}Y (n, γ)
^{95}Nb	35 d	β^-	765 (100)	^{94}Zr (n, γ)
^{99}Mo	67 h	β^-	740 (12)	^{235}U (n, fission)
^{113}Sn	115 d	EC [a]	255 (18)	^{112}Sn (n, γ)
^{125}I	60 d	EC [a]	27 (138); 35 (7)	^{124}Xe (n, γ)
^{131}I	8.1 d	β^-	364 (82)	^{235}U (n, fission)
^{131}Cs	9.7 d	EC [a]	Xe X rays	^{130}Ba (n, γ)
^{140}Ba	12.8 d	β^-	537 (34)	^{235}U (n, fission)
^{153}Gd	242 d	EC [a]	Eu X rays	^{152}Gd (n, γ)
^{195m}Pt	4.1 d	IT [c]	67 (84); 99 (12)	^{194}Pt (n, γ)
^{198}Au	2.7 d	β^-	412 (95)	^{197}Au (n, γ)

[a] EC = electron capture.
[b] This is the result of a double reaction: the first reaction is the activation of lithium: ^6Li (n, ^3H)^4He. This reaction generates ^3H, which then reacts with the ^{16}O present.
[c] IT = isomeric transition (transition to a lower nuclear energy level without a change in mass).
[d] 100 % corresponds to emission of one photon per nuclear decomposition.

3.2. Cyclotrons and Other Accelerators

Charged-particle accelerators are high-voltage machines capable of accelerating charged particles to the desired energy levels. For biomedical and chemical purposes, the machines used need only accelerate charged particles to less than 100 MeV, although radionuclide production has also been accomplished in machines that accelerate charged particles to higher energies. However interesting such high energy machines may be, they were built originally for purposes other than radionuclide production, and their availability is thus very limited.

Cyclotrons. The most commonly used system is the cyclotron [9], which is an accelerator whose path has been shaped into a spiral by means of a magnetic field applied perpendicularly to the plane of motion of the ions. It was originally invented by ERNEST O. LAWRENCE in 1930. The particles most commonly accelerated in a cyclotron are protons, deuterons, and ^3He and ^4He (i.e., α) particles. During operation, a charged particle in a uniform magnetic field moves

along a circular orbit with a period of revolution independent of its velocity. The magnetic field causes a bending of the particle's trajectory and guides it along a circular path while an electrostatic potential difference between the electrodes supplies energy to the particle itself, progressively taking it into orbits of greater and greater radius without any change in the frequency of revolution. Thus, particles follow a spiral path from the center of the machine (where the ion source is located) to the maximum radius where they are either used to strike a target directly (internal target) or extracted from the cyclotron for use outside (external target) [11].

The radionuclides formed in charged-particle reactions are all neutron-deficient. Most are short-lived, and many are positron emitters (see ⟶ Isotopes, Natural – Stable Isotopes as Radioisotope Precursors), which makes them of particular interest for biomedical studies. Indeed, it is worth recalling here that the first biological studies with radiocarbon were done with ^{11}C, the positron-emitting isotope of carbon ($t_{1/2}$ = 20.4 min) made at LAWRENCE's cyclotron, before M. D. KAMEN produced the much longer-lived (and reactor-produced) ^{14}C [12].

The most important field of application for particle accelerators is in biomedicine. This includes radionuclide production, cancer treat-ment with fast neutrons and proton beams, and radiological studies. Use of such radionuclides requires a more complex environment than that for handling the radionuclides produced in reactors, inasmuch as it is generally necessary to integrate radionuclide production with its utilization. This is especially true of the “physiological” radionuclides (^{11}C, ^{13}N, and ^{15}O), which must be produced at or extremely near the site of utilization. However, a much greater variety of radionuclides can be prepared with the aid of a cyclotron, and the resulting specific activities are much higher than those of materials from reactors.

Cyclotrons can be grouped into four main categories, classed according to the maximum energies of the accelerated protons: < 10 MeV, 10 – 18 MeV, 18 – 40 MeV, and > 40 MeV. While the smaller (“baby”) cyclotrons are usually single-beam machines, all the others can accelerate both protons and deuterons (the latter at half-proton energy). Acceleration of ^{3}He and ^{4}He particles requires energies > 18 MeV. Higher-energy cyclotrons (> 40 MeV) are required for the production of fast-neutron and proton beams suitable for cancer chemotherapy. In addition, and with sufficient knowledge of the excitation function, higher beam energies are often degraded to the desired level at the entry to the target. The thickness of the target is also crucial, to ensure that energy deposited inside the target falls within the desired range.

Charged-particle accelerators are utilized extensively for the production of several neutron-deficient radionuclides that are applied in the synthesis of radiopharmaceuticals, mainly involving the following four positron emitters, whose $t_{1/2}$ values are given in parentheses: ^{11}C (20.4 min), ^{13}N (10 min), ^{15}O (2 min), and ^{18}F (110 min). One of the main applications of such positron-emitting radionuclides takes advantage of the two 511-keV annihilation photons emitted in coincidence with an angular correlation of 180°, the positron – emission tomography (PET) technique [13]. Cyclotrons used for such purposes are usually two-particle machines, yielding proton energies ≤ 20 MeV and deuteron energies ≤ 10 MeV, with a maximum beam current of 60 μA.

Many other nuclear reactions can be accomplished with cyclotrons, including the (p, α), (p, d), (p, γ), (p, *x*n), (p, *x*p*x*n), (d, α), (d, p), (d, *x*n), (d, *x*p*x*n), (^{3}He, p), (^{3}He, *x*n), (^{3}He, *x*p*x*n), (α, p), (α, *x*n), and (α, *x*p*x*n) reactions, where *x* is an integer, usually between 1 and 6. The nuclear reactions occurring in a cyclotron are varied, and each nuclear reaction induced by a charged particle has an optimum energy range for the bombarding particle to produce the best results in terms of yield and purity of the desired product. The choice of nuclear reaction, knowledge of the excitation functions, proper timing, and the use of appropriate radiochemical methods determines the quality of radionuclide preparation. When radionuclides are produced in accelerators they are generally obtained as *no-carrier-added* materials [14], thereby assuring very high specific activity. (The term “no-carrier-added” expresses the fact that no stable isotope of the radionuclide under production has been introduced during any of the steps in the generation of that radionuclide.)

Choice of a suitable *target* is perhaps the most important single factor in selecting a reaction for the production of a radionuclide — or for that matter, of a radiopharmaceutical — in a cyclotron. Because of intense heating caused in the target and its containment as a result of beam-energy degradation, target materials must have high melting points, high thermal conductivities, and they must be chemically inert. In order to minimize damage to the target, and in order to obtain a uniform production of radionuclides, the target should be of the highest purity attainable, and it must be properly cooled [15]. A major concern with respect to operating a cyclotron efficiently is removing the heat generated on the target during its bombardment, with temperatures that may exceed 1000 °C. This is accomplished by circulating cold deionized water or air around the target, and by using stable, heat-conducting target materials.

Target holders are usually made of aluminum. This metal is easy to work with, leads to minimum build-up of induced radioactivity, and displays good heat transfer. Copper is an alternative; although it has good mechanical and thermal properties, it is subject to increased build-up of radioactivity following target bombardment. The target's windows are usually made of thin foils of aluminum, Mylar (PETP film), Havar (Co-based alloy), tungsten, or tantalum. Windows must be as thin as possible to avoid beam degradation, yet strong enough to resist internal target pressure. Target materials may be solids, liquids, or gases. To facilitate the separation of radionuclides generated during activation, radiochemists have devised gaseous targets that yield solid radionuclides and solid targets for producing gaseous radionuclides. Developed mainly for the production of the PET radionuclides ^{15}O, ^{13}N, ^{11}C, and ^{18}F, gas targets are also used for the preparation of ^{123}I (from ^{124}Xe), ^{81}Rb (from ^{82}Kr), and other species. A discussion of gas target techniques for radionuclide production with small cyclotrons is given in [16]. Sometimes a stack of different metal foils or a double chamber can be used to produce several radionuclides simultaneously. Sometimes it is necessary to recycle a target material after processing, especially if it is expensive, but most of the common targets support continuous production of specific radionuclides, with automatic separation of the products.

One problem sometimes encountered is the fact that the radionuclide formed may react with the walls of the target. Thus, in the original scheme for production of ^{18}F using the ^{20}Ne(d, α) reaction, most of the (hot) ^{18}F generated reacted with the

walls of the gas target. This problem was solved by use of a nickel target, the walls of which had been passivated with fluorine gas, together with addition of a small amount of cold $^{19}F_2$ to maintain the ^{18}F as ^{18}F - F_2 [17].

Even when the target is of high purity, isolation and purification of radionuclides is usually required subsequent to their production. The most common chemical separation methods are precipitation, co-precipitation, solvent extraction, chromatography, electrolysis, and ion exchange. In addition, physical methods are used (i.e., mass separation, vacuum distillation, vacuum deposition, or phase changes). Gas targets are obviously the most desirable, because they allow rapid and efficient recovery of products with high specific activity and good radiochemical and radionuclidic purity [15].

Van de Graaff Accelerators. *Single-stage Van de Graaff* accelerators have been used effectively for the preparation of radionuclides due to their very high beam currents [18]. *Tandem Van de Graaff accelerators* with higher energies display lower beam-current capacity. One of the advantages of Van de Graaff accelerators is that their deuteron and proton energies are equivalent, whereas with a cyclotron the deuteron energy is only half the proton energy. A Tandem Van de Graaff accelerator can supply a PET center with useful quantities of a variety of radionuclides, including ^{11}C, ^{13}N, ^{15}O, and ^{18}F. All of these can be prepared with (p, n) or (d, n) reactions, and the reactions themselves have cross sections of at least 100 millibarn over most of the energy ranges of interest. With such cross sections, the thick-target yields for single half-life bombardment with 1 μA (a beam readily available in nearly all Van de Graaff accelerators) are about 30 mCi for 6 MeV incident energy and 100 mCi for 12 MeV. This is within the order of magnitude required for medical applications (taking into account losses accompanying synthesis) [19]. Historically, cyclotrons have been the accelerators of choice because of their high beam currents. For long-lived radionuclides this is always advantageous, since products not used immediately can be stored for later use. For short-lived radionuclides, however, a Tandem Van de Graaff accelerator is preferable, as storage of the products is clearly impossible, and the Van de Graaff accelerator can generate as much activity as required for immediate use.

Electron Accelerators. An electron accelerator is another type of device that can and has been used to prepare radionuclides via photonuclear reactions. Its advantage over the (positively) charged particle accelerators is that both neutron-deficient and neutron-rich radionuclides can be produced. Also, bremsstrahlung causes less heating of the target than does charged-particle bombardment, simplifying both target preparation and heat removal. Sometimes a higher radionuclidic purity can be achieved through a photonuclear reaction than with a reaction involving a charged particle. For example, the yield of ^{155}Tb in a (γ, n) reaction after irradiation with an electron beam of 25 MeV (beam current 10 μA) for 20 h is about 3.0 μCi μA^{-1} h^{-1} g^{-1}. The purity of the product from such a reaction is usually very high. Some powerful electron linear accelerators achieve E_{max} values of 500 MeV and maximal beam power of 250 kW [20].

Another example of a photonuclear reaction for producing a carrier-free radionuclide of high purity is the preparation of ^{123}I free of any ^{124}I contamination (which is very detrimental to its medical use) via the sequence of reactions:

$$^{124}Xe(\gamma, n)^{123}Xe\ (EC, \beta^+)\ ^{123}I \tag{3.8}$$

The reaction threshold here is 10.5 MeV, and the energy for maximum reaction cross section is 15.5 MeV. An overenergetic beam can generate the undesirable ^{124}I via the ^{126}Xe (γ, n)^{124}I reac-tion with a threshold of 17.3 MeV. Therefore, bremsstrahlung beam energies higher than 30 MeV may be detrimental. However, by reducing the proportion of ^{126}Xe in the enriched ^{124}Xe, it is possible to increase the electron energy, and hence the yield of ^{123}I, while retaining high radionuclidic purity [21]. Other reactions for producing ^{123}I are described in Section Radionuclide Production from Cyclotrons.

Neutron Generator. Another powerful application of neutron beams takes advantage of a “neutron generator,” which can be utilized for the preparation of certain short-lived radionuclides, especially in laboratories without access to a reactor or a cyclotron. A neutron generator is a source of high-energy fast neutrons, and is based on a reaction between deuterium and tritium:

$$^{3}H(d, n)^{4}He \tag{3.9}$$

This reaction is exothermic and produces high-energy neutrons with a kinetic energy of about 14 MeV. A practical generator consists of an ion source, a target, vacuum control, a cooling system, and various power circuits for the production of an accelerated deuteron beam which is caused to impinge on a tritium target. Two types of such generators are available: the first operates with a demountable target, making it possible to change targets, while the second operates with a sealed tube. The former is used mainly in research, where the ability to change targets and study other nuclear reactions is advantageous. The latter is used where only a fixed flux of neutrons is required. An example of sealed tube device is the Kanan generator with an output of 10^{11} neutrons per second. The maximum neutron flux available for irradiating small samples is 2×10^{10} n cm^{-2} s^{-1}. Because of the high energy of the resulting neutrons (14 MeV), it is possible with this device to conduct (n, 2n), (n, p), and (n, α) reactions. Due to the fact that the cross section for 14 MeV reactions is relatively low, and the fluxes available are several orders of magnitude lower than with nuclear reactors and cyclotrons, large quantities of material must be activated in order to prepare useful quantities of radionuclides. For this reason the main applications of this system are in activation analysis and neutron-beam therapy [22].

Worldwide Availability of Accelerators. Many small (< 10 MeV protons), medium (10 –40 MeV), and larger (40 – 70 MeV) cyclotrons are now available in both industry and in a number of developing nations. In addition, many 70 MeV proton accelerators are now available in a number of countries where they are used for commercial and research purposes, yielding beam intensities ≤ 200 μA. Proton beams have a greater range in matter than either deuterons or α particles, so their efficiency in the production of radionuclides is relatively high. One of the reasons for promoting cyclotrons in developing countries is to provide alternatives to reactor-produced technologies. Overall yields are usually higher from a reactor than with a simple accelerator, but the cost of installing, operating, and ultimately decommissioning a

reactor and its complex ancillary facilities is presumed to be considerably higher than that of installing and operating a modern accelerator and radiochemistry facility [23].

Descriptions of some of the larger accelerators follow, demonstrating variability in terms of beam strength and production capability.

Los Alamos Meson Physics Facility (LAMPF) has a powerful (800 MeV, 300 – 550 μA) proton beam. This beam is accelerated through a straight tunnel about 1 km long on a collision course with nine isotope targets. The beam accelerates to 252 000 km/s, 84 % of the velocity of light, and at the end of the line crashes into stacked targets [24].

Linear Accelerator, Brookhaven National Laboratory (LINAC) is another high-energy, high-current linear accelerator with a 200 MeV, 40 – 70 μA proton beam, a part of which is deflected to targets in the Brookhaven LINAC Isotope Production (BLIP). The main portion of the beam, however, goes to the alternating gradient synchrotron, where the particles are accelerated in a 0.5 mile (0.804 km) orbit for high-energy physics experiments [24].

Tri-University Meson Facility of the Atomic Energy Commission of Canada (TRIUMF –AECL) complex is housed at the University of British Columbia. It contains a high-energy, negative-ion separated-sector cyclotron, which delivers proton beams ≤ 500 MeV and beam currents of 140 μA.

Another powerful medical cyclotron is the sector-focusing frequency-modulated cyclotron of the *Gustaf Werner Institute* in Uppsala, Sweden, which permits acceleration of protons up to 200 MeV and other light ions to corresponding energies, as well as spallation neutrons. Its max-imum external proton current in the high-energy range is about 10 μA, and ≤ 40 μA as an external beam for the lower-energy range [25].

One of the most powerful European production facilities is the *Swiss Institute of Nuclear Research* (SIN) in Villigen. This facility attempts to utilize a > 200 MeV proton beam to induce spallation reactions as a means of high-level radionuclide production. Such spallation reactions usually do not yield radionuclides with the quality standards already established for accelerator-produced radionuclides [15].

Other important large accelerators are the *Hammersmith cyclotron* in London, the *Variable Energy Cyclotron* (VEC) of Harwell in Didcot, United Kingdom, the 86-inch cyclotron at the *Oak Ridge National Laboratory* (ORNL), the 600 MeV proton cyclotron of the *CERN synchrocyclotron,* and the 400 MeV proton beam of the *Fermi National Lab* in Batavia, Illinois. More detailed lists of available cyclotrons are provided in [26] and [27].

3.3. Radionuclide Production from Reactors

Methods for radionuclide production using reactors have been described extensively [28], [29]. Basically, a suitable target is placed inside the reactor for a preset period of time. The irradiation time can vary from 2 – 4 half-lifes for radionuclides with half-lifes of less than 2 weeks to weeks or months for longer-lived radionuclides. The target is removed from the reactor at the EOB and then processed. Typical irradiation times range from days for most radionuclides (e.g., 5 – 7 d to activate ^{98}Mo to ^{99}Mo at a flux of 2×10^{14} n cm^{-2} s^{-1}) to weeks (two weeks to activate ^{194}Pt to ^{195m}Pt at a similar flux, 30 – 60 d to activate ^{124}Xe to ^{125}Xe, followed by another 60 d to allow the ^{125}Xe to decay to ^{125}I), months, or years (e.g., to produce ^{3}H, $t_{1/2}$ = 12.5 a), and ^{14}C ($t_{1/2}$ = 5640 a). Given so much variability, a common way of expressing practical yields is to define the activity that can be achieved at half-saturation. For example, the activation of ^{152}Sm to form ^{153}Sm has a cross section of 200 barn. The isotopic abundance of ^{152}Sm is only 26.6 %, and activation of natural samarium would lead to a mixture of radioisotopes. Approximately 370 GBq of ^{153}Sm can be produced by the irradiation of 10 mg of Sm_2O_3 (made from > 99 % enriched ^{152}Sm) at a flux of 10^{14} n cm^{-2} s^{-1} for 46 h (half-saturation). Production of ^{153}Sm with higher specific activities is possible only in a high-flux reactor (flux $\geq 2\times10^{15}$ n cm^{-2} s^{-1}), which should be sufficient for use in clinical protocols requiring administration of minute amounts (< 10 mg) of labeled proteins for therapeutic applications [29]. In another example, irradiation of 1 g of natural palladium for 13 h in a flux of 10^{14} n cm^{-2} s^{-1} resulted in 20 mCi of ^{109}Pd that still required purification. A much purer radionuclide was obtained by the irradiation of enriched ^{108}Pd, leading to a ^{109}Pd with specific activity of about 2500 Ci/mol [29].

Thus, the *direct* (n, γ) *activation* of enriched target molecules with σ > 100 barn in reactors with high thermal neutron fluxes should provide specific activities sufficient for many therapeutic radionuclide applications. It is clear from the above examples that abundant quantities of radionuclides can be prepared in reactors with relatively modest fluxes if enriched targets (σ > 10 barn) are used. Examples of β-emitting radionuclides with $t_{1/2}$ values of < 15 d produced in nuclear reactors include ^{165}Dy, ^{109}Pd, ^{188}Re, ^{166}Ho, ^{153}Sm, ^{90}Y, ^{186}Re, ^{177}Lu, ^{169}Er, and ^{32}P (see also Table 1) [10].

Alternatively, it is possible to achieve high activities (both total and specific) of *no-carrier-added reactor-produced radionuclides* through indirect (n, γ) sets of reactions, e.g.:

$$^{124}\text{Xe (n, }\gamma)^{125}\text{Xe} \longrightarrow {}^{125}\text{I}$$
$$^{104}\text{Ru (n, }\gamma)^{105}\text{Ru} \longrightarrow {}^{105}\text{Rh}$$
$$^{130}\text{Te (n, }\gamma)^{131}\text{Te} \longrightarrow {}^{131}\text{I}$$
$$^{198}\text{Pt (n, }\gamma)^{199}\text{Pt} \longrightarrow {}^{199}\text{Au}$$

One advantage of this approach is that the reaction yields need not be high, since high activities can be achieved by

irradiating large quantities of target nuclei, followed by chemical purification of the desired radionuclide [7]. In the irradiation of ^{130}Te, the intermediate ^{131}Te ($t_{1/2}$ = 25 min) decays to ^{131}I ($t_{1/2}$ = 8 d). Because this radionuclide is nonisotopic with the target, it is, in theory, "carrier-free" (or — more accurately — "no-carrier-added"). Specific activities > 10^6 Ci/mol can be obtained by this reaction [8]. Other β-emitting radionuclides produced by indirect activation are ^{77}As, ^{149}Pm, ^{199}Au, ^{177}Lu, and ^{111}Ag (see also Table 1).

Fission. The energy liberated in a fission process is much higher than that liberated in β decay: part of it goes to the newly formed fragments, and the rest goes to the accompanying free neutrons. Since heavy nuclei have a large proportion of neutrons, fission fragments tend to contain more neutrons than necessary for their stability, and the nuclei stabilize themselves by β decay. When ^{235}U absorbs a thermal neutron, it fragments into a large number of nuclei, distributed around two peaks of mass 100 and mass 130. Several of the radionuclides formed are of significant medical, industrial, and radiochemical interest. Some of the key fission products from ^{235}U and their cumulative yields are:

^{90}Sr as a "pure beta" source	5.89 %
^{137}Cs as a γ source	6.18 %
^{99}Mo as a generator parent	6.14 %
^{131}I for labeling and diagnosis	2.84 %

While long-lived fission-product nuclides such as ^{137}Cs and ^{90}Sr can be conveniently recovered from fuel-reprocessing wastes, medium- and short-lived radionuclides are usually produced by irradiation of a uranium (natural or enriched) target in the reactor. Since the fission product gives rise to a mixture of radionuclides, some of which are highly toxic (e.g., ^{90}Sr and ^{137}Cs), stringent purification procedures must be employed in order to recover radionuclides of interest with the requisite purity [30]. Fission reactions may also be regarded as a type of neutron activation, because they are generally induced by neutron capture.

Spallation is another process yielding large numbers of neutrons. It is a two-step process that occurs as a consequence of the impact of high energetic nucleons onto a nucleus. In the first stage of events, called the "intra-nuclear cascade", highly energetic nucleons escape from the nucleus and trigger a similar cascade in another nucleus. The nucleus left behind by the cascade particles is in a highly-excited state and loses most of its energy by evaporating off other particles: mainly neutrons, but also to a rapidly decreasing extent protons, deuterons, tritons, and α particles. The result of this process is generally an active nucleus that decays further through γ emission and β^+ decay. The spallation reaction is basically endothermic [31], and it can only occur when the incident particles have energies > 100 MeV. Production of radionuclides at very large accelerators (LAMPF, BLIP) occurs by spallation.

Successive Neutron Capture. Successive capture of two or more neutrons is of interest for the production of certain radionuclides, such as ^{38}S, which can be used as a parent for ^{38}Cl in a nuclide generator.

$$^{36}S(n,\gamma)^{37}S(n,\gamma)^{38}S \rightarrow {}^{38}Cl$$

$$^{194}Pt(n,\gamma)^{195m}Pt(n,\gamma)^{196}Pt$$

In some instances, however, successive neutron-capture reactions are a source of radionuclide impurities (e.g., formation of ^{126}I from ^{125}I and ^{199}Au from ^{198}Au [7], or the burnup of ^{195m}Pt ($t_{1/2}$ = 4 d) to ^{196}Pt, where the σ for production of ^{195m}Pt is 0.1 barn, but that of its burn up is 20 000 barn!) [32].

Szilard – Chalmers Recoil-Enrichment Processes. When stable compounds of certain elements are irradiated with thermal neutrons in an (n, γ) reaction, a significant fraction of the radionuclide produced appears in a chemical form different from that of the target because chemical bonds are cleaved due to the high energy of the radionuclide formed. This fraction is known as the "recoil chemical form," and it can be readily separated from the target by simple radiochemical techniques. The fraction of the total activity of the radionuclide produced that appears in the recoiled chemical form is known as the Szilard – Chalmers recoil enrichment recovery. For example, free ^{82}Br can be obtained from a $KBrO_3$ target with a 91 % yield and 2×10^4 enrichment [7].

Special Radionuclides Produced in Nuclear Reactors. The three most widely used radionuclides in nuclear medicine are ^{99m}Tc, obtained from the β decay of ^{99}Mo and used in 85 % of all in vivo nuclear medicine studies; and ^{125}I and ^{131}I, where ^{125}I accounts for 95 % of all in vitro nuclear medicine procedures, while ^{131}I remains the second most widely used radionuclide for in vivo studies. All three radionuclides are produced, either directly or indirectly, in nuclear reactors.

Production of Molybdenum-99. Two major methods exist for the production of ^{99}Mo at high specific activity: direct irradiation of molybdenum trioxide and fission of uranium, either enriched or natural.

When MoO_3 is irradiated at fluxes exceeding 2×10^{14} n cm^{-2} s^{-1} for 5 – 7 d and then extracted in aqueous ammonia, specific activities of > 5 Ci/g $^{99}MoO_3$ of > 99.5 % radionuclidic purity are obtainable. To ensure even higher specific activities, enriched $^{98}MoO_3$ can be used.

In the *uranium fission process*, natural uranium or enriched ^{235}U can be employed in the form of metal, U – Al alloy, or uranium oxide. If 90 %-enriched ^{235}U is irradiated at a neutron flux of 2×10^{13} n cm^{-2} s^{-1} for 3 – 7 d, the yield of ^{99}Mo is about 15 Ci/g. The ^{99}Mo can be extracted in HNO_3 and passed through an alumina column. ^{99}Mo is adsorbed onto the column, which is than washed to remove radionuclidic contamination, resulting in ^{99}Mo obtained of specific activity > 50 Ci/mg and > 99.9 % radionuclidic purity [7].

Production of Iodine-125. For the production of ^{125}I, natural xenon is used containing about 0.1 % ^{124}Xe in the target. It is filled under pressure into an capsule and irradiated at a neutron flux of 2×10^{14} n cm^{-2} s^{-1} for 30 – 60 d. The yield of ^{125}I is approximately 0.2 Ci/g. This material should be allowed to stand for 60 d before processing to reduce ^{126}I levels to < 2 %. Then the xenon gas is sublimed out of the cooled ampule, and ^{125}I is extracted with dilute NaOH. The final specific activity is > 15 Ci/mg and product purity is > 99.9 %.

Production of Iodine-131. For ^{131}I production a TeO_2 target is irradiated, from which ^{131}I is obtained by wet or dry distillation [7].

3.4. Radionuclide Production from Cyclotrons

Radionuclides of major biomedical interest that are produced in cyclotrons include the physiological radionuclides (^{11}C, ^{13}N, ^{15}O, and ^{18}F) as well as a number of other key neutron-deficient nuclides. Table 1 summarizes some of the key cyclotron-produced radionuclides, based on [10]. An analysis of the relative merits of various nuclear processes using a cyclotron to produce radionuclides for generators is presented in [33].

Table 2. Examples of radionuclides produced in cyclotrons (this tabulation is based on a more extensive table in [10]) [a]

Radionuclide produced	$t_{1/2}$	Mode of decay	Main γ energies emitted, keV (% abundance)	Selected mode of production
^{11}C	20.3 min	β+	511 (200)	^{11}B (p, n)
^{13}N	9.9 min	β+	511 (200)	^{12}C (d, n)
^{15}O	123 s	β+	511 (200)	^{14}N (d, n)
^{18}F	110 min	β+	511 (200)	^{20}Ne (d, α)
^{22}Na	2.62 a	β+, EC	511 (180); 1275 (100)	^{24}Mg (d, α)
^{28}Mg	21.2 h	β−	31 (90); 400 (30); 950 (30)	^{26}Mg (α, 2p)
^{30}P	2.5 min	β+	511 (200); 2230 (0.5)	^{27}Al (α, n)
^{38}K	7.7 min	β+	511 (200); 2170 (100)	^{35}Cl (α, n)
^{48}Cr	23 h	EC	116 (98); 310 (99)	^{50}Cr (d, 5n)
^{51}Mn	45 min	β+, EC	511 (194); 1560 (34)	^{52}Cr (p, 2n)
^{52}Fe	8.2 h	β+, EC	165 (100); 511 (112)	^{50}Cr (α, 2n)
^{58}Co	71.3 d	β+, EC	511 (30); 810 (99)	^{58}Ni (n, p)
^{62}Zn	9.1 h	β+, EC	511 (186); 669 (81)	^{60}Ni (α, 2n)
^{64}Cu	12.8 h	β+, EC, β−	511 (38)	^{65}Cu (p, pn)
^{74}As	18 d	β+, EC, β−	511 (59); 596 (61); 635 (14)	^{71}Ga (α, n)
^{75}Br	1.7 h	β+, EC	285 (92); 511 (180)	^{75}As (α, 4n)
^{77}Br	57 h	β+, EC	240 (30); 511 (1.5)	^{75}As (α, 2n)
^{81}Rb	4.7 h	β+, EC	511 (26); 1110 (42)	^{82}Kr (p, 2n)
^{85m}Kr	4.2 h	β−, IT	150 (75); 305 (13)	^{84}Kr (d, p)
^{85}Sr	64 d	EC	514 (100)	^{86}Rb (p, n)
^{97}Ru	2.9 d	EC	215 (91); 324 (8)	^{95}Mo (α, 2n)
^{99}Mo	67 h	β−	740 (12)	^{98}Mg (d, n)
^{111}In	2.8 d	EC	173 (89); 247 (94)	^{111}Cd (p, n)
^{123}I	13.3 h	EC	159 (83)	^{127}I (p, 5n)
^{127}Xe	36.4 d	EC	172 (22); 203 (65); 375 (20)	^{133}Cs (p, 2p,5n)
^{201}Tl	74 h	EC	Hg X-rays; 81 (98); 168 (8)	^{200}Hg (d, n)

[a] For abbreviations see footnote to Table 3.

Production of Oxygen-15 and Fluorine-18. ^{15}O and ^{18}F can be prepared by a variety of methods. One involves their

simultaneous production using 30 MeV protons, in which a double liquid-chamber target is irradiated [34]. Such a system provides the option of producing $H_2^{15}O$ and either ^{13}N or ^{18}F with a single proton beam. Irradiating natural water in the front chamber leads to $H_2^{15}O$ by the ^{16}O (p, pn) reaction, while the rear silver-liquid chamber efficiently generates either ^{13}N by the ^{16}O (p, α) reaction or ^{18}F by the ^{18}O (p, n) reaction. This combination target ensures rapid and high-volume production of the three most fully-validated and widely-used radiopharmaceuticals in clinical PET. Other useful reactions for ^{15}O production include ^{14}N(d, n), ^{16}O (p, d), and ^{15}N (p, n), where the former is most widely practiced. The radiopharmaceuticals produced on-line by these reactions are $H_2^{15}O$, $C^{15}O_2$, and $C^{15}O$, respectively [35]. Two additional methods are applied for no-carrier-added ^{18}F production: proton irradiation of a natural magnesium target or of enriched ^{27}Al. ^{27}Al produces ^{18}Ne via Al (p, 2 α2n)^{18}Ne, the latter decays ($t_{1/2}$ = 1.7 s) to ^{18}F and can be used in a generator system [36], [37]. A very useful method for preparing electrophilic ^{18}F is the (d, α) irradiation of natural neon in a gas target [17].

Production of Carbon-11. ^{11}C can be made using the ^{12}C (^3He, α), ^{10}B (d, n), and ^{14}N (p, α) reactions [38]. In the latter case a gas target is irradiated with 18 MeV protons and then combined with traces of O_2 to yield $^{11}CO_2$. This target can also be used as a starting material for $^{11}CH_3I$, a suitable precursor for the methylation of organic molecules [39]. ^{11}C can also be profrom a linear accelerator, with CO_2, liquid cyclohexane, or liquid glacial acetic acid as target materials. The specific activities achieved in such a production are reported to be suitable for clinical duced by using a 26 MeV, 100 μA electron beam applications [40].

Production of Molybdenum-99. ^{99}Mo was produced by a cyclotron long before it was used as a diagnostic radiopharmaceutical. The direct production of curie quantities of ^{99m}Tc and 100 mCi quantities of ^{99}Mo on a cyclotron were first suggested by BEAVER and HUPF [41], using an isotopically-enriched ^{100}Mo target. RANDA and SVOBODA [42] used the ^{98}Mo (d, p) ^{99}Mo reaction for the same purpose. The use of natural molybdenum targets was later studied by ALMEIDA and HELUS [43] applying a maximum proton energy of 25 MeV. Thin foils of metallic molybdenum (purity > 99.95 %) were stacked and used as targets in a water-cooled aluminum holder. Despite the relatively low abundance of ^{100}Mo in the target (9.6 %), the use of natural molybdenum is appropriate for production of no-carrier-added ^{99}Mo by one of the following cyclotron-reactions, in addition to the neutron activation reactions discussed above:

$$^{100}\mathrm{Mo(p,2p)}^{99}\mathrm{Nb(15s)} \rightarrow {}^{99}\mathrm{Mo}$$

$$^{100}\mathrm{Mo(p,pn)}^{99}\mathrm{Mo}$$

$$^{100}\mathrm{Mo(n,2n)}^{99}\mathrm{Mo}$$

with such natural molybdenum targets the production yields are about 20 mCi μA^{-1} h^{-1} [23].

Production of Iodine-123. ^{123}I of high purity can be obtained either directly or indirectly from a cyclotron. In the *direct approach* ^{123}I is produced by 25-MeV-proton irradiation of enriched (> 95 %) ^{124}TeO, but contamination with ^{124}I (up to 5 %) is unavoidable. When used in medicine the 386 – 665 keV γ radiation of ^{124}I causes a degradation of scintigraphic images and contribute to the radiation burden of the patient [43]. In the *indirect method,* 60-MeV protons irradiate elemental iodine, NaI, or KI to produce ^{123}Xe, or else they are used to bombard a ^{124}Xe target:

$$^{127}\mathrm{I(p,5n)}^{123}\mathrm{Xe} \rightarrow {}^{123}\mathrm{I}$$

$$^{127}\mathrm{I(d,6n)}^{123}\mathrm{Xe} \rightarrow {}^{123}\mathrm{I}$$

$$^{124}\mathrm{Xe(p,2n)}^{123}\mathrm{Cs} \rightarrow {}^{123}\mathrm{Xe} \rightarrow {}^{127}\mathrm{I}$$

$$^{124}\mathrm{Xe(p,pn)}^{123}\mathrm{Xe} \rightarrow {}^{123}\mathrm{I}$$

The advantages of using ^{127}I as a target are its 100 % isotopic abundance and low cost, but a significant disadvantage is that it requires a high-energy cyclotron. The advantage of using a ^{124}Xe target is that it utilizes protons of < 42 MeV, but a disadvantage is the high cost of ^{124}Xe gas [44]. In another unusual procedure, ^{123}I is produced by a *beam of 25 MeV electrons* in a 10-h irradiation of a tantalum target enriched with ^{124}Xe. About 200 mCi of ^{123}I accumulate through a photofission reaction, and this material can be used for medical purposes after appropriate extraction [45]. A powerful linear accelerator is capable of producing high-purity ^{123}I by the *spallation process.* One such device is the Canadian TRIUMF, which can generate 1-Ci quantities. The spallation yield of this reaction can compete with yields from low-energy cyclotrons by the use of very thick spallation targets [46].

Production of Thallium-201. ^{201}Tl is one of the most useful neutron-deficient radionuclides produced by a cyclotron. It is used extensively as a tracer in cardiac perfusion studies, although it is a relatively expensive radiopharmaceutical. The most common production method involves the ^{203}Tl (p, 3n)$^{201}Pb \longrightarrow {}^{201}Tl$ reaction [3.44]. The material is produced by bombarding enriched (95 %) ^{203}Tl in the form of the sulfate, yielding 2.2. mCi μA^{-1} h^{-1} with a beam energy of 22 MeV. Other production reactions entail proton bombardment of enriched (> 99 %) ^{205}Tl for the ^{205}Tl (p, 5n)$^{201}Pb \longrightarrow {}^{201}Tl$ reaction or enriched (95 %) ^{206}Pb. Yields and impurities in the three reactions are very similar (see also Section Radionuclide Generators).

Production of Selenium-73. ^{73}Se is increasingly replacing ^{75}Se ($t_{1/2}$ = 120 d), which has been the most widely-used radionuclide of selenium for radiotracer and clinical studies. The long physical $t_{1/2}$ and decay characteristics of ^{75}Se provide a highly absorbed radiation dose to the patient and lead to images of poor quality. ^{73}Se is a more suitable tracer from the standpoint of radiation dosimetry, with a half-life of 7.1 h and applicability to both PET and single photon emission computer tomography (SPECT) studies. It emits both β^+- and a 361-keV γ radiation of 97 % abundance. The reactions ^{70}Ge(^{4}He, *x*n) and ^{75}As (p, 3n) have been used for its production: starting with the 26-MeV α particles available from compact cyclotrons, the reported production yield is 1 mCi μA^{-1} h^{-1}, and with a 55-MeV proton beam the reaction yields 20 mCi μA^{-1} h^{-1}. The radiochemical yield of ^{73}Se is > 75 % in less than 90 minutes [48].

Production of Cobalt-55. ^{55}Co-bleomycin has been used for scanning malignant tumors (e.g., lung cancer and brain metastases), and is considered superior to ^{67}Ga citrate for that purpose. ^{55}Co ($t_{1/2}$ = 18 h) is practical for PET studies, because it decays mainly (81 %) by positron emission. A relatively simple method for preparing it, is by applying a 12 MeV indirect deuteron energy for a ^{54}Fe(d, n) reaction, yielding 1.7 mCi μA^{-1} h^{-1} of ^{55}Co. Other applicable reactions are ^{56}Fe (p, 2n) (natural iron target with 40 MeV incident proton energies) and ^{58}Ni(p, α) (natural nickel foil with 20 MeV protons), followed by separation of the ^{55}Co on an anion-exchange column [49].

Production of Radioactive Gallium Isotopes. ^{66}Ga has replaced other radiogalliums in clinical studies. Accumulation of ^{67}Ga citrate in soft-tumor tissues has promoted its use for the detection of tumors and inflammatory diseases. In addition, ^{68}Ga, a positron emitter with a $t_{1/2}$ of 68 min, has been used in conjunction with tomography after chelation to a number of pharmaceuticals. However, the short half-life of ^{68}Ga limits its suitability in lengthy procedures, so that longer-lived PET gallium radionuclides have been sought. ^{66}Ga has a $t_{1/2}$ of 9.4 h, and 56.5 % of its decay is by positron emission. It can be produced by α particle bombardment of natural copper via the ^{63}Cu(α, n) reaction, with a maximum cross section of 667 mbarn at 16.6 MeV. The extent of long-lived ^{67}Ga contamination at EOB is 0.25 %. If the incident energy is increased beyond 18 MeV, the contamination by ^{67}Ga increases with no significant gain in ^{66}Ga yield. The yield of ^{66}Ga at 18 MeV incident energy is about 700 μCi μA^{-1} h^{-1} [50].

Production of Bromine-77. ^{77}Br is produced by proton irradiation of molybdenum metal. It is separated from the target by co-distillation of the radiobromine species with 0.5 – 1.0 mg of added stable chloride carrier. The solids are trapped in aqueous silver nitrate, the silver is subsequently removed with a cation-exchange column. In a typical ^{77}Br preparation, 100 g of molybdenum metal foil is irradiated for a period of 4 – 7 d, with a chemical yield of 80 – 90 %; the amount of ^{77}Br removed is 1 – 2 Ci [26].

Production of Copper-67. ^{67}Cu is a pure β emitter, the absorbed dose of its radiation in a tumor of 30 – 40 cell diameters is calculated to be uniform. It is therefore used for radiotherapy, especially when chelated to tumor-associated monoclonal antibodies. The suggested nuclear reactions for its production, in quantities relevant to nuclear medicine, include ^{68}Cu (p, 2p), ^{68}Zn (d, 2pn),^{67}Zn (d, 2p),^{64}Ni (α, p),^{67}Zn (n, p), and As (p, spallation), utilizing a natural zinc target. After irradiation with 200 MeV protons, ^{67}Cu is purified via electrodeposition, ion-exchange, dry distillation, and extraction. The following reactions can also be used: ^{68}Zn (p, 2p), ^{70}Zn (p, α), and ^{67}Zn (n, p). These methods provide sufficient quantities of ^{67}Cu with high specific activity and adequate radioactive purity. The production yield of ^{67}Cu at 200 MeV proton energy is 4.2 μCi μA^{-1} h^{-1} [51]. In a 3-d irradiation with 200 MeV protons, 100 mCi can be produced from a 4-g zinc target. The ^{67}Cu can be then separated by electrolysis, which results in a separation factor of 1×10^6. Up to 10 Ci can be produced with irradiation by 800-MeV protons for 2 weeks [7].

Production of Rubidium-81. ^{81}Rb is the parent radionuclide for ^{81m}Kr, used in cardiac studies. Its production represents an example in which the yield often exceeds local requirements even with nonoptimized targetry and irradiation conditions. The method generally employed involves proton or deuteron irradiation of krypton gas of natural isotope composition to yield ^{82}Kr (p, 2n)^{81}Rb, ^{83}Kr (p, 3n)^{81}Rb, ^{84}Kr (p, 4n)^{81}Rb, and ^{82}Kr (d, 3n)^{81}Rb. Other possibilities are ^{85}Rb (p, 5n)^{81}Sr $\longrightarrow$ ^{81}Rb, ^{79}Br (α, 2n), and ^{81}Br (^{3}He, 3n). All methods produce ^{81}Rb in overwhelming quantities. It has also been shown that nickel and aluminum targets are satisfactory for ^{81}Rb production: the recovery yield of ^{81}Rb on an aluminum target is about 3.5 mCi μA^{-1} h^{-1}, and that on a nickel target is about 6.0 mCi μA^{-1} h^{-1}, both with proton irradiation at 20 – 40 μA · h. Nickel seems to be superior to aluminum for the cyclotron targetry utilized in ^{81}Rb production, giving consistent and satisfactory yields [52].

3.5. Radionuclide Generators

Generator systems provide a common and convenient method for obtaining a variety of γ- and β-emitting radionuclides at a patient's bedside. From the practical perspective they offer a desirable alternative to cyclotrons in the case of short-lived radionuclides. In a generator system, a short-lived radionuclide (a “daughter”) is obtained from a longer-lived “parent”, which is adsorbed onto a solid-phase carrier, usually an alumina column, inside an appropriate shield [53], [54]. Efficient separation of the “daughter” from the “parent” is a basic requirement for such a system. As soon as the daughter radionuclide is formed it can be eluted from the column, leaving the parent behind to generate more of the desired radionuclide. Nuclear reactors are the major source for generator “parent” compounds, due to their high neutron flux and relative ease of target preparation. Since most of the labeling procedures involving low protein concentrations are performed with a single conjugated ligand, it is imperative that a daughter radionuclide eluted from the generator has a high specific activity and is free of contamination from other trace metals that may compete with the major radionuclide on a limiting number of chelating agents [29].

One of the prerequisites for a generator system is that there be no (or minimal) breakthrough of the parent radionuclide or the column chemical into the eluent. Breakthrough is defined as the extent of contamination of the eluate by the parent radionuclide, and depends on the distribution coefficient of the parent, on the support material, and on the chemical stability of the support column under high radiation doses [55]. The maximum permissible parent concentration in the eluate depends on its toxicity, half-life, and dose as delivered to the patient in a medical application. It is usually less than 10^{-3} % per elution [56].

Separation of a daughter radionuclide from its parent can be accomplished by a continuous (steady-state) or discontinuous (bolus) method. The *continuous method* involves elution of the daughter radionuclide from the generator as it is formed, and its direct use. The *bolus method* involves one-time elution of all the available daughter activity. Such discontinuous elution can be repeated after an appropriate intervening build-up time. This method is employed when the daughter is *not* a short-lived radionuclide, as in the case of ^{99m}Tc. The theoretical maximum daughter activity continuously available from a generator is a function of the half-life of the daughter radionuclide: for ^{81m}Kr ($t_{1/2}$ = 13 s) the value is 533 μCi/s, while for ^{99m}Tc ($t_{1/2}$ = 21 600 s) it is only 0.32 μCi/s [55]. Several of the more important generator systems are described below, and others are characterized in Table 3.

Table 3. List of selected generator-produced radionuclides (this tabulation is based on a more extensive table in [10]) [a]

Parent radionuclide	$t_{1/2}$	Decay	Mode of production	Daughter radionuclide	$t_{1/2}$	Decay	Major photon energies, keV, (% abundance)
^{28}Mg	21.2 h	β−	^{26}Mg (^{3}H, p)	^{28}Al	2.3 min	β−	1780 (100)

[a] For abbreviations see footnote to Table 3.

The $^{99}Mo \longrightarrow {}^{99m}Tc \longrightarrow {}^{99}Tc \longrightarrow {}^{99}Ru$ Generator. ^{99}Mo is produced commercially in a reactor by a ^{98}Mo(n, γ) reaction, by fission of ^{235}U(n, fission), or by neutron-activation of natural molybdenum (see Fig. 19 and The ^{99}Mo ⟶ ^{99m}Tc ⟶ ^{99}Tc ⟶ ^{99}Ru Generator.). Practical considerations usually limit the irradiation time of the parent to three daughter half-lifes (i.e., ca. 7 d). Under these conditions about 53 % of the ^{99}Mo and more than 92 % of the ^{99m}Tc decays before the irradiation is complete. At the end of bombardment, the ^{99}Tc: ^{99m}Tc ratio in the irradiated target is about 14: 1. Most of the ^{99}Tc is washed out during generator manufacture. Because of the branching decay of ^{99}Mo and the decay of ^{99m}Tc by isomeric transition, ^{99m}Tc solutions always contain some ^{99}Tc. The amount varies considerably depending on the production method, general performance, and the time between production and use. The sensitivity of particular kits to ^{99}Tc depends on the ligand, the amount of usable Sn^{2+}, and the ratio of technetium to ligand. If elution or extraction efficiencies are high, any ^{99}Tc is reduced within about two elutions to an insignificant level that is maintained in subsequent elutions. With efficiencies < 40 %, however, the ratio of ^{99}Tc to ^{99m}Tc increases with each elution. Although the activity of ^{99}Tc is negligible compared with that of ^{99m}Tc, even when present in amounts that are 10 or 100 times higher, the two isomers react in the same way with the components of a radiopharmaceutical kit. The labeling and imaging of some radiopharmaceuticals are adversely affected by a high atomic ratio of ^{99}Tc to ^{99m}Tc [57].

The $^{81}Rb \longrightarrow {}^{81m}Kr \longrightarrow {}^{81}Kr \longrightarrow {}^{81}Br$ Generator. The radionuclidic production process for this generator used in pulmonary studies involves irradiation of natural krypton gas in a target chamber by the ^{82}Kr (p, 2n) reaction and dissolution of the ^{81}Rb formed with water, steam, or saline solution. The resulting solution can then be transferred into a hot cell for loading into the generator. ^{81m}Kr is washed out of the generator by continuous elution with humidified air, and is used to produce a sequence of images from multiple breaths of the patient, enabling reconstruction of time – activity images. A systematic evaluation has been carried out of the excitation functions for formation of several rubidium radionuclides in proton-induced nuclear reactions on natural krypton, ^{82}Kr, and ^{83}Kr, with special reference to the production of ^{81}Rb for generating ^{81m}Kr. The method of choice for the preparation of ^{81}Rb ⟶ ^{81m}Kr generator system is the ^{82}Kr (p, 2n) process on highly enriched ^{82}Kr. The optimum energy range for production is 19 –27 MeV, and the thick-target yield of ^{81}Rb amounts to 48 mCi μA^{-1} h^{-1}. Due to the high yield of the proton process sufficient quantities of ^{81}Rb can be prepared even with a cyclotron in the energy range of 20 MeV [58], [59].

The $^{52}Fe \longrightarrow {}^{52m}Mn \longrightarrow {}^{52}Mn \longrightarrow {}^{52}Cr$ Generator. *^{52m}Mn* has shown potential as a myocardial imaging agent and for evaluating the efficiency of therapeutic intervention on ischemic perfusion. ^{52m}Mn decays by isomeric transition and positron emission to a much longer-lived radionuclide. Its high-flux 511 keV annihilation γ-rays make it ideal for imaging in emission-computed tomography. *^{52}Fe* itself has nuclear-medicine merit as an erythropoietic marrow agent, because it is the only radionuclide of iron with decay properties suitable for imaging applications. It can be produced by α, ^{3}He, and proton reactions on ^{50}Cr, ^{52}Cr, or ^{55}Mn. Using particle energy ≤ 70 MeV the maximum thicktarget yield is 160 μCi μA^{-1} h^{-1}. Higher particle energies can yield up to 3.3 mCi μA^{-1} h^{-1} at a beam current of 70 μA. A stack of foils irradiated and processed at the LAMPF can produce as much as 1 Ci at EOB after 16 h irradiation. This allows production of multicurie generators for hospital use. A similar method for ^{52}Fe production is based on a nickel target, which is simpler to use [27], [60].

The $^{113}Sn \longrightarrow {}^{113m}In \longrightarrow {}^{113}In$ Generator. ^{113m}In has found considerable application in nuclear medicine with its convenient half-life of about 100 min, a monoenergetic γ radiation of 393 keV, and the long half-life of the parent ^{113}Sn (118 d). Only 2 – 3 generators of this pair need be purchased per year to obtain a continuous supply of the daughter, compared to weekly procurement of a ^{99m}Tc generator. ^{113m}In has been used in various radiopharmaceuticals in scanning the brain, blood-pool, reticuloendothelial system, and kidney. The parent ^{113}Sn may be produced either by ^{113}In (p, n) or by ^{112}Sn(n, γ) reactions and is obtained in relatively high purity [54].

The $^{82}Sr \longrightarrow {}^{82}Rb \longrightarrow {}^{82}Kr$ Generator. This generator, used for cardiac PET imaging, contains about 100 mCi of ^{82}Sr ($t_{1/2}$ = 25 d) and lasts 4 – 6 weeks. It is the single most important cardiovascular imaging generator, because ^{82}Rb is useful for perfusion imaging in diagnosing coronary artery disease, acute myocardial infarction, and ischemia. The major production methods of ^{82}Sn are Mo (p, spallation), Rb (p, *x*n), and Kr (α, *x*n). Because of the short $t_{1/2}$ of the daughter radionuclide (76 s), serial PET studies can be conducted at 5 – 10 min intervals. If provided in 100 – 200 mCi amounts, the generator can provide adequate ^{82}Rb elution yields for three months. If ^{82}Sr is produced by spallation of a molybdenum target with 800 MeV protons (as in LAMPF), it may contain a 1 : 1 ratio of isotope ^{85}Sr ($t_{1/2}$ = 65 d), so for practical purposes this should be considered as a $^{82/85}$Sr column. The radiation doses to the skeleton of a 70 kg person from 1 μCi of ^{82}Sr/^{82}Rb and ^{85}Sr are 71 and 7.6 mrad, respectively [24], [61].

The $^{68}Ge \longrightarrow {}^{68}Ga \longrightarrow {}^{68}Zn$ Generator. ^{68}Ge is obtained by the ^{69}Ga (p, 2n) reaction in high yield. The practicality of ^{68}Ga emerges from its ability to form chelates with proteins and other compounds, and from its long $t_{1/2}$, which permits its continued use for about a year. Medical interest in this radionuclide developed from its potential for imaging thrombi formation with labeled platelets and imaging atheromas with bifunctional chelate-labeled lipoproteins. Since ^{68}Ga is obtained from the generator as a chelate of EDTA,an extra step must be incorporated into its preparation if ionic gallium is required [136].

The $^{191}Os \longrightarrow {}^{191m}Ir \longrightarrow {}^{191}Ir$ Generator. The radionuclide ^{191m}Ir ($t_{1/2}$ = 5 s) is suitable for pediatric radionuclide angiography, for the quantitation of shunts and ejection fractions, and for the diagnosis of congenital cardiovascular

malformations. Thermal neutron irradiation of enriched ^{190}Os for production of ^{191}Os is feasible at a flux as low as 4×10^4 n cm^{-2} s^{-1}. ^{191}Os can then be purified by conversion to OsO_4 and isolation by distillation and solvent extraction. Contamination with ^{192}Ir is produced, and this must be eliminated prior to medical use. Multicurie amounts can be prepared by irradiating enriched ^{190}Os in a high-flux reactor for 3 – 4 d. Long periods of irradiation may result in increasing levels of induced radionuclide impurities and decreasing yields of ^{191}Os due to neutron-capture (burn up) of this radionuclide [62], [63].

The $^{195m}Hg \longrightarrow {}^{195m}Au \longrightarrow {}^{195}Au \longrightarrow {}^{195}Pt$ Generator. This generator is suitable for first-pass and steady-state radionuclide cardiac angiography. Its attractiveness stems from its availability as a carrier-free single-photon emitter in a biologically-inert state, suitable for vascular imaging. Dynamic functional studies, especially cerebral blood-flow measurements, require repeated patient investigation at short intervals, and the advantage of ^{195m}Au over ^{81m}Kr is the fact that it is not quickly eliminated by the lungs after IV bolus. Also, ^{195m}Au emits predominantly 262-keV γ quanta and gives a clean spectrum for analysis. Typical production yield at a proton energy of 32 MeV is 5.4 mCi μA^{-1} h^{-1}. For medical use, such a preparation should be relatively free of the high-energy contaminants ^{195m}Hg (560 keV) and ^{195}Hg (1.17 MeV, $t_{1/2}$ = 9.5 h) [64], [65].

The $^{224}Ra \longrightarrow {}^{212}Pb + {}^{212}Bi \longrightarrow {}^{208}Pb$ Generator. Increased awareness of the therapeutic potential of α emitters, especially short-lived ones, has prompted the development of generators for such radionuclides. ^{212}Pb and ^{212}Bi are suited to use as such radiotherapeutic agents due to their relatively short half-lifes and appropriate α-particle emissions. The parent ^{224}Ra is available from a long-lived parent ^{228}Th, and can be isolated on a generator that produces the daughters in good yield and low breakthrough. ^{212}Bi, which has a half-life of 61 min, and is conveniently available in large quantities from this generator, may be bound to proteins via a bifunctional chelate. It is retained in various tumors, and a 25 mCi generator suffices for clinical use. ^{212}Bi alone delivers 24 500 g · rad/mCi, and the ^{212}Pb 250 000 g · rad/mCi [66].

Another useful way of obtaining the *radiolead isotope ^{211}Pb* is from a gaseous generator daughter via the $^{227}Ac \longrightarrow {}^{223}Ra \longrightarrow {}^{219}Rn \longrightarrow {}^{211}Pb$ reaction. In this reaction ^{211}Pb is produced in a generator system that utilizes distillation of the intermediate daughter ^{219}Rn from ^{223}Ra. The ^{223}Ra is precipitated as a stearate to permit its isolation from ^{227}Ac by cation exchange. While the yield of the system is only about 10 %, the radionuclidic purity is very high [67].

The $^{109}Cd \longrightarrow {}^{109m}Ag \longrightarrow {}^{109}Ag$ Generator. This generator is used primarily for pediatric imaging and blood flow studies. Special interest in it stems from the fact that a hospital can obtain several years of use from a single generator because the physical half-life of the parent radionuclide is 453 d. The daughter ^{109m}Ag produces low-energy γ-rays (88 keV) and has a 4-s half-life [54].

The $^{72}Se \longrightarrow {}^{72}As$ Generator. The product of this generator is a positron emitter, and may be applicable to the labeling of monoclonal antibodies and for toxicological studies. It is mentioned here because of the rich organic chemistry of arsenic, which can easily be incorporated into various chemical structures. Due to the intermediate half-life of ^{72}As ($t_{1/2}$ = 26 h), it can also be used for brain imaging, while the longer half-life of the parent ($t_{1/2}$ = 8 d) permits such a generator to last for 3 – 4 weeks [24].

The $^{115}Cd \longrightarrow {}^{115m}In \longrightarrow {}^{115}In$ Generator. ^{115m}In emits 300-keV conversion electrons and has a range of approximately 1 mm in soft tissue. This short range and a $t_{1/2}$ of 4.5 h makes it advantageous for radiation synovectomy.

The $^{201}Pb \longrightarrow {}^{201}Tl \longrightarrow {}^{201}Hg$ Generator. The ^{201}Tl radionuclide is accelerator-produced and used for evaluating regional myocardial metabolism (see also Section Radionuclide Production from Cyclotrons). Because of significant decay losses of ^{201}Tl during transportation an unusual generator was designed — unusual in the sense that the $t_{1/2}$ of the parent (9.4 h) is much shorter than that of the daughter (73.5 h). In a typicial generator, separation of the ^{201}Tl on an ion-exchange Dowex resin yields 400 mCi of ^{201}Tl from 4 Ci of ^{201}Pb, in a small extraction volume, with no detectable radioactive lead breakthrough and < 2 µg/mL of carrier thallium [68].

The $^{128}Ba \longrightarrow {}^{128}Cs \longrightarrow {}^{128}Xe$ Generator. Production of ^{128}Cs from spallation reactions, using a 85 MeV proton bombardment on a cesium chloride target, was reported as early as 1950. Similarly, production of ^{128}Cs by high-energy proton beams (> 200 MeV) has also been reported, using a $CsNO_3$ target. ^{128}Cs has potential applications for positron tomography, particularly for imaging the myocardium (where it is being considered as a potassium analogue for its trapping mechanism), and for measuring regional blood flow. Its $t_{1/2}$ is short enough to allow its use in sequential studies with PET systems. Cyclotron production of the pair Ba ⟶ Cs in transient equilibrium has yielded 3.1 mCi μA^{-1} h^{-1} with a 2.3 g/cm^2 thick CsCl target and a proton energy of 67 MeV. Ion exchange can be used for preparing highly-purified ^{128}Cs for the production of this generator [69].

[Top of Page]

4. Detection of Ionizing Radiation and Radionuclides

Horst Miska

The basis for using radioactive materials in research, medicine, and industry is the fact that these substances can be

detected easily and with high sensitivity through the radiation they emit. This nuclear radiation has the ability to ionize atoms and molecules, so that even the tiniest quantities of a radioactive material can be detected by physical methods. These detection limits cannot be achieved with chemical methods.

Chapter Detection of Ionizing Radiation and Radionuclides begins with a brief description of the types of ionizing radiation and its interactions with matter, then proceeds on to a discussion of detection methods and instruments. A detailed discussion of ionizing radiation is given in [70-74]; details on instruments can be found in manufacturers' catalogs and operating instructions [75-84] contains a summary of European manufacturers and suppliers of detectors.

4.1. Types of Ionizing Radiation

As explained in Chapter Introduction, radioactive materials can emit alpha (α), beta (β), or gamma (γ) radiation. The neutrino radiation (ν) emitted in every β decay event is of no importance for practice; it is extremely difficult to detect and is therefore ignored in the discussion that follows.

In α *decay*, the mass of a heavy nucleus decreases by four atomic mass units and an α particle (^{4}He nucleus) is emitted. It has a mass of M = 4 and a positive charge of two. The energy released in the decay event is precisely fixed for every nuclide, so α particles have a discrete energy distribution. In β^+ *and* β^- *decay* a proton is converted to a neutron or a neutron to a proton and a positron or electron is emitted. β particles thus have a charge of one unit, positive or negative; the mass is ca. 1/1836 times that of a proton or neutron. Although the energy available in a β decay event is fixed for each nuclide, β particles have a continuous energy distribution because the neutrino that is emitted simultaneously takes up part of the energy.

These types of nuclear radiation are directly ionizing by virtue of their charge. The *gamma radiation* that usually follows α or β decay is a purely electromagnetic phenomenon; it has no charge and no (rest) mass and thus does not directly cause ionization. Because the excited state of the nucleus emitting γ radiation is exactly defined, γ radiation has a discrete energy spectrum. In a similar way, the *neutrons* released in nuclear fission, nuclear fusion, and other nuclear reactions cannot directly ionize matter since they are uncharged. Again, the energies available to the neutron are well-defined for every event, but the fact that several particles are involved in neutron-generating reactions means that neutrons do not generally exhibit a discrete energy spectrum.

The types of radiation discussed up to this point originate in radioactive materials or may, as in the neutron case, come from mixed sources (e.g., polonium/beryllium). *X-rays*, used chiefly in medical diagnosis, are emitted as bremsstrahlung when accelerated electrons are stopped in matter; this is a purely electromagnetic radiation like γ radiation, but because of the way in which it is produced, its spectrum is continuous with a maximum energy corresponding to the kinetic energy of the accelerated electrons. These bremsstrahlung X-rays are accompanied by characteristic X radiation having discrete energies, which depend on the anode material used. Like visible light, this characteristic radiation originates in the atomic electron shell (excess binding energy is released when electrons drop into the vacancies that have been created in the inner shells by electron bombardment).

Electromagnetic radiation generated by electron accelerators with final energies of several MeV is no longer called X radiation but *bremsstrahlung.* Its maximum energy equals the electron energy, and its spectrum is continuous like that of X-rays.

Other forms of ionizing radiation are produced by *high-energy particle accelerators*, either as desired radiation for use in fundamental research, industry, and medicine (therapy), or as an undesired side effect when the particle beam is stopped. The interactions and detection of these types of radiation are not discussed here, although the techniques are similar in principle to those covered.

Finally, part of our natural radiation exposure is due to *cosmic rays*, which originate when energy is transformed by nuclear fusion in the sun and stars. Direct cosmic radiation comprises the rays that penetrate to the Earth's surface. Its principal constituents are muons (μ), light charged particles similar to electrons and detected in the same way. In addition, cosmic radiation produces many varieties of secondary radiation, which are of interest here only because they make up part of the background radiation measured with detecting instruments.

4.2. Detection Methods

When radiation passes through matter, the particles of radiation are subject to interactions whereby they give up energy to the matter and are either stopped or absorbed. Because of the electromagnetic interaction of *charged particles*, these particles are persistently slowed by ionization and excitation of the atoms and molecules in the material involving a large number of single events. *Uncharged* (*neutral*) *radiation*, in contrast, is subject to “all or nothing” interactions; in only one event the primary radiation particle vanishes, i.e., it gives up its total kinetic energy (or at least a substantial part of the energy) all at once.

The instruments and methods used to detect radiation depend on the types of interaction involved and the objectives pursued.

4.2.1. *Interactions Between Ionizing Radiation and Matter*

4.2.1.1. *Energy Loss of Charged Particles*

The energy loss suffered by charged particles as a result of ionization and excitation heavily depends on the properties of the particles and only slightly on those of the irradiated matter. The energy loss dE over a path length dx can be approximated to:

$$\frac{dE}{dx} = -\varrho C \frac{Z}{A_r} \frac{z^2}{v^2} \left[\log \frac{m_e v^2}{I(1-\beta^2)} - \beta^2 \right] \quad (4.1)$$

Here, C is a constant, ϱ is the density of the material, Z is its atomic number, and A_r its relative atomic mass; z and v are the charge and velocity of the particle, respectively. The expression shown in square brackets varies slowly with velocity (as the logarithm) and describes the increase of energy loss at relativistic energies.

If the velocity v of the particle is expressed in terms of the mass m and the kinetic energy $T_p = 1/2\, mv^2$, the following expression results. (It has been further simplified, includes a new constant C', and is normalized to the density of the material):

$$\frac{dE}{\rho dx} = -C' \frac{Z}{A_r} \frac{mz^2}{T_p} \left[\log \frac{m_e v^2}{I(1-\beta^2)} - \beta^2 \right] \quad (4.2)$$

Particles having kinetic energy of the same order as their rest mass energy (such as electrons at a few MeV) have a minimal ionizing effect. The differential energy loss $dE/\varrho\, dx$ for such particles is almost 2 MeV/(g/cm^2). The loss increases sharply at lower energies and is proportional to the z^2 and m of the particle. For α particles with a given kinetic energy, the energy loss is therefore roughly 10^4 times larger than for slow electrons (β particles) having the same kinetic energy because the following holds: $(z_\alpha/z_\beta)^2 = 4$ and $m_\alpha/m_\beta \approx 8000$ (4×1836).

The differential energy loss by ionization and excitation is shown in Figure 20.

Figure 20. Energy loss of charged particles

Ionization losses: a) α Particles in silicon; b) Protons in silicon; c) Electrons in air; d) Electrons in lead Radiative losses: e) Electrons in lead; f) Electrons in airDifferent energy scales are employed for electrons (MeV) and for heavy particles (GeV)

Because of the persistent stopping by ionization and excitation, charged particles have a well-defined maximum range, which in principle depends on their energy alone. The differential energy loss is greatest toward the end of the range; the ionization here is most intense. The range for β particles in air is ca. 3 m, whereas that for α particles is ca. 10 cm. The corresponding ranges in water or tissue are less than 1 cm and 1/10 mm, respectively. Because α particles are completely stopped by a layer corresponding in thickness to a sheet of paper, the instrument used to detect α radiation must have an extremely thin entrance window.

4.2.1.2. *Bremsstrahlung Production*

For light charged particles having a kinetic energy T_p of the same order as their rest mass m_0c^2 (or higher), energy loss due to bremsstrahlung production also plays a major role. This energy loss, normalized to the material density, is

$$\frac{dE}{\rho dx} = -C'' \frac{Z^2}{A_r} \frac{T_P}{m^2} \left(\text{for } T_p > m_0 c^2\right) \quad (4.3)$$

Z^2 represents a strong material dependence, and the radiative loss also decreases as $1/m^2$, so that this energy loss chiefly affects electrons. The bremsstrahlung loss for cosmic-ray muons, which have a mass roughly equal to 200 electron masses, is therefore just 1/40 000 of the loss for electrons.

The “radiation length” t_0 has been introduced in order to describe the energy loss of electrons. This material-dependent quantity is the distance over which bremsstrahlung losses reduce the energy of an electron to $1/e$ times its initial value. The radiation length is a function of the mean Z of the material. It is about 36 cm for water, 9 cm for aluminum, and only 0.5 cm for lead. Thus fast electrons must be stopped by a material with a long radiation length (i.e., small Z) if the production of bremsstrahlung radiation is to be minimized or if all the energy transferred to the material (detector) is to be determined in particle spectroscopy.

4.2.1.3. *Energy Loss of Neutrons and Gamma Quanta*

Neutrons and γ quanta do not experience energy loss by ionization, excitation, or by bremsstrahlung since they have no charge.

Neutrons. Neutrons transfer only part of their energy to nuclei in elastic or inelastic collisions. An elastic collision imparts only kinetic energy to the nucleus; in an inelastic collision, the nucleus is also excited, and this energy is later released as γ radiation. The energy transferred to the recoil nucleus is greater the smaller its mass. In the extreme case, a neutron can give up all of its energy to a hydrogen nucleus ($A_r = 1$); on average, a neutron loses half of its kinetic energy in a collision with a proton. Materials with low nuclear mass, i.e., with a high hydrogen content (e.g., paraffin or polyethylene), are therefore used to stop and detect neutrons. The kinetic energy of the recoiling proton or nucleus is transferred by ionization in the material over a short distance, since these particles have high ionizing power by virtue of their large mass and charge (see Eq. 4.2).

Neutrons decelerated in this way, now having low energies, are then absorbed by nuclei because the cross sections are generally proportional to 1/*v*. They initiate a variety of reactions:

1. In (n, γ) reactions, the binding energy of the captured neutron is subsequently emitted in the form of γ radiation
2. In (n, p) and (n, α) reactions, a proton (p) or α particle is emitted after the capture of the neutron
3. In the (n, f) reaction, which possibly occurs only with some superheavy nuclei, a nuclear fission takes place after the neutron capture

The (n, p) and (n, α) reactions are, therefore, preferred for the detection of slow neutrons, since protons and α particles are easy to detect. The (n, f) reaction is suitable for extremely sensitive neutron detection because of the amplifying action of nuclear fission events (neutron multiplication, high-energy fission fragments).

Gamma Radiation and Bremsstrahlung. The main interactions of γ and bremsstrahlung radiation with matter are the photoeffect, Compton scattering, and pair production.

The *photoeffect* (photoelectric effect) involves the complete absorption of a γ quantum, which transfers its energy to a stronlgy bound electron (usually a K electron) in the material which is then expelled. In order to conserve momentum and energy, the nucleus must also acquire recoil energy. The vacancy in the K shell is then refilled, either with the emission of characteristic X radiation or Auger electrons. If this X radiation is also absorbed in another photoeffect in the material (of the detector), the γ quantum has then given up its total energy to charged particles in the material. The cross section for the photoeffect is proportional to Z^4 to Z^5 of the material and also to 1/*E* to $1/E^{3.5}$ of the radiation.

In *Compton scattering*, a γ quantum gives up part of its energy to a (free) electron; the scattered γ escapes in a direction different from its original one. The energy transfer reaches maximum in backscattering (180°), where the electron acquires an energy T_e:

$$T_e(\theta = 180\,^\circ) = \frac{E_\gamma}{1 + 511\text{keV}/2E_\gamma} \tag{4.4}$$

The Compton-scattering cross section is proportional to *Z* (i.e., to the number of electrons in the material) and $1/E_\gamma$.

Pair production is the inverse process to bremsstrahlung. An electron – positron pair is created in the material. A nucleus must be involved in the process as a collision partner, which acquires recoil energy. The formation of the electron and positron requires 511 keV each; the remainder is imparted to these as kinetic energy. Above the threshold of $2\,m_e$ = 1022 keV, the pair production cross section is proportional to Z^2 and to log E_γ. The distance t_P over which the number of γ quanta decreases to 1/*e* by pair production is $t_P = (9/7)t_0$. This result makes it clear that the process is related to bremsstrahlung production.

The electron and positron are stopped by ionization in the material. Together with an electron, the positron forms positronium, a species similar to a hydrogen atom (see Section Interaction between Positrons and Matter), which rapidly transforms its rest mass energy to radiation (annihilation radiation). Usually the results is a pair of γ quanta, each with energy 511 keV, propagating in opposite directions. Three γ quanta are formed in rare cases, the sum of their energies being 1022 keV.

With coordinates *Z* versus E_γ, Figure 21 shows the regions in which the several effects are dominant. The lines do not represent sharp boundaries but rather indicate where the reaction cross sections are just equal. The photoeffect dominates at low γ energy and high atomic number of the material, while pair production is dominant at high energy and high *Z*. The Compton effect is the most frequent interaction at small *Z* and moderate energy. High-*Z* materials are thus needed for the shielding and detection of γ radiation, because the γ quanta should be absorbed by the photoeffect rather then scattered by the Compton effect.

Figure 21. Interaction of γ-rays with matter

Cross sections for the photoeffect and Compton effect are equal (. . . .); cross sections for the Compton effect and pair production (- - -) are equal

Because they do not undergo persistent stopping by ionization, no well-defined range can be identified for γ and neutron radition. Instead, a half-value layer or tenth-value layer is defined as the thickness of material after which only half or a tenth of the initial particles are still present. The quantity usually cited in radiation protection is the material thickness behind which the dose rate is only a tenth of the original value.

4.2.2. *Detector Types*

Ionizing radiation can be detected by different techniques: collecting and registering the charge carriers liberated in the material by ionization, or studying other defects produced by the radiation. Common to all methods, however, is an amplification step in order to detect the energy deposited in the material by a particle or quantum.

Detector types are classified by material: gas ionization detectors, scintillators, semiconductor detectors, and solid-state detectors. Which one is selected will depend on what is required; compromises are often necessary, because generally

one type cannot meet all the requirements.

4.2.2.1. *Gas Ionization Detectors*

The simplest detector is the gas ionization type, usually called counter tube (see Fig. 22).

Figure 22. Schematic of a counter tube

a) Source; b) Protective screen; c) Window; d) Counter wire; e) Insulator

The radiation enters the active volume of the counter through a window (c). The chamber is most often filled with a special counter gas (filling gas). The case of the counter tube is at ground potential, whereas a positive voltage is imposed on the counter wire (d) in order to attract the electrons liberated in the gas. If the voltage on the wire is so low that just those electrons that are liberated by radiation in the chamber reach the wire, the device is referred to as an *ionization chamber.* The electron current flowing to the wire is proportional to the energy deposited in the chamber by radiation. The current is extremely small and must be electronically amplified before detection.

If the wire is held at a higher voltage, the electrons are accelerated until they can produce further ionization, so that the number of electrons reaching the wire increases in an avalanche-like fashion when propagating to the wire; that is, the electrons undergo gas multiplication. In Figure 23, the gas multiplication factor (gas amplification), that is, the number of electrons reaching the wire divided by the number of electrons liberated in the active volume by the radiation, is plotted versus the applied voltage.

Figure 23. Response of counter tubes

The gas multiplication factor at a given voltage is constant in the *proportional counter region*; typical values range from $10^6 – 10^8$. The number of electrons detected is proportional to the energy deposited in the gas by the radiation. The pulse height or pulse shape can thus be used to distinguish pulses initiated by α particles from those initiated by β particles or γ quanta. The particle energy can also be determined, so the proportional counter can also be employed in spectroscopy.

The voltage can be further increased until enough photons are formed in the gas to produce photoelectrons in the gas and the walls. Ultimately, the entire volume of gas is ionized in a counter pulse (similar to what happens in a fluorescent tube). Regardless of the energy transferred from the particle to the gas, an extremely large pulse is generated. This pulse is followed by a long detector dead time. A device operated in this mode is called a *Geiger – Müller counter.*

Ionization chambers are often used to measure a local dose rate; when in the form of pen dosimeters, they can also measure individual dose. *Proportional counters* find use in contamination detectors and in the measurement of activities in air, for example, that of radioactive inert gases. Special filling gases such as BF_3 also permit the detection of neutrons, in this case via the (n, α) process. *Geiger – Müller counter tubes* are employed chiefly in dose-rate meters because of their robustness and small size.

4.2.2.2. *Scintillation Detectors*

It was discovered early on that α particles initiate flashes of light when they impact on certain materials such as zinc sulfide. Nowadays, scintillation detectors are made from special transparent materials, in which a large fraction of the energy deposited in the material by the particles is emitted in the form of light. Traces of other substances are generally added in order to enhance the light output. Figure 24 shows a schematic diagram of a scintillation detector.

Figure 24. Schematic of a scintillation counter

a) Source; b) Scintillator; c) Photocathode; d) First and e) last dynodes in photomultiplier; f) Anode. The voltage divider supplying the dynodes and the anode is merely indicated

The intensity of the emitted light is proportional to the energy deposited in the scintillator by the particle. Falling on the photocathode (c) of a photomultiplier, this light sets free electrons, which are accelerated toward the successive dynodes (d – e) by the applied voltage. Every impact of an electron on a dynode generates several electrons. In this way, electron multiplication factors of 10^6 or more can be achieved, depending on the number of dynodes and the high voltage imposed on the tube. The total number of electrons arriving at the anode is thus a measure of the energy given up by the particle.

Charged-particle spectroscopy is usually performed with scintillators made of organic compounds (e.g., naphthalene or anthracene), called plastic scintillators. Because of their high hydrogen content, these devices can also detect neutrons via their recoil protons.

Gamma Radiation. The detection of γ radiation, however, requires a material of high density and high atomic number. Scintillators made of sodium iodide or cesium iodide are used for this purpose; a new development are oxides, e.g.,

bismuth germanate ($Bi_4Ge_3O_{12}$, BGO) having a high mean *Z* and a high density. The detector efficiency depends heavily on the size of the scintillator. In the laboratory, scintillators measuring up to 3×3 inch (ca. 76 mm in diameter and height) are common, but scintillators ranging up to several liters in volume are available for special applications, such as the detection of high-energy bremsstrahlung.

The variety of interactions between γ radiation and matter means that a γ detector will have a complex energy spectrum. If the γ quantum gives up its total energy to the detector in a single event (photoeffect) or in several events over a short time, the event will register in the total absorption line or photopeak. On the other hand, a high-energy quantum may impart its energy to the detector by pair production, and one or both of the 511 keV quanta emitted afterwards as annihilation radiation may escape detection. Since the energy of the escaping quanta is not registered in the detector, such an event is recorded under the single-escape or double-escape peak, respectively; these lines lie 511 and 1022 keV below the photopeak. A Compton continuum is present in addition to these lines; it arises because quanta escape from the detector after a Compton scattering event and their energies are not detected. What is more, the experimental geometry may result in other lines produced by backscattering. All in all, the interpretation of γ spectra is very complex, especially if the source exhibits more than one γ line.

Liquid scintillators (LSC) are used to detect low-energy β radiation such as that from ^3H or ^{14}C. Such a scintillator consists of organic compounds to which the specimen material (e.g., biological or medical samples with ^3H or ^{14}C as tracers) is added. This configuration ensures that the total β energy will be absorbed in the scintillator. The specimen – scintillator liquid is observed by two or more photomultipliers connected in coincidence, in order to reduce the background rate due to multiplier noise.

4.2.2.3. *Semiconductor Detectors*

Since researchers have succeeded to fabricate large-volume semiconductor crystals, these materials have gained importance in the spectroscopy of ionizing radiation. In semiconductor detectors, the *n* layer is doped much higher than the *p* layer, so that the thicknesses of the respective depletion layers are drastically different. The highly doped *n* layer then forms a thin entry window for the radiation, while the depth of the depletion region in the *p* layer can be increased by applying a reverse bias (similar to that carried out in an electrical semiconductor diode). The depletion region forms a zone almost free of charge carriers, which then becomes a “solid-state ionization chamber.” The charges liberated in this volume by ionization are delivered to a charge-sensitive preamplifier, whose output signal is then proportional to the energy deposited in the semiconductor by the particle.

Silicon surface-barrier detectors (SSBDs) are employed for spectroscopy involving *charged particles*, such as electrons, protons, deuterons, or α particles. If it is desired to distinguish between particle species, a telescope consisting of one or more thin detectors with a thick detector mounted behind is used. The energy loss of the particle is measured in the thin detector(s), while the sum of all pulses is proportional to the total particle energy. Since the energy loss depends on the particle's charge and mass (Eq. 4.2), it can be identified once the loss is known.

Germanium detectors are used to detect γ *radiation.* Earlier these devices were doped with lithium to form Ge(Li) detectors, but these detectors are being replaced by high-purity germanium (HP – Ge) detectors that are now available and easier to use. Because the lithium diffuses out of the Ge(Li) at room temperature, such devices must be continuously cooled with liquid nitrogen; HP – Ge diodes, on the other hand, are cooled only during measurement and solely to reduce noise and improve the resolution. These detectors make high-resolution γ spectroscopy possible, so that the setup illustrated in Figure 25 permits nuclide identification based on the emitted γ radiation.

Figure 25. Block diagram of γ spectroscopy setup (nuclide identification)

Data analysis can be performed with a multichannel analyzer (MCA), or the analog pulses from the amplifier can be fed to a converter (ADC), digitized, and then input to a computer system for analysisa) Bias supply; b) Preamplifier; c) High-purity germanium; d) Dewar vessel with liquid nitrogen; e) Amplifier; f) Multichannel analyzer; g) Analog – digital converter; h) Personal computer

4.2.2.4. *Basic Properties of the Detector Types*

Along with ease of use and cost, the following properties must be considered when choosing a detector type: detector efficiency, energy resolution, and (for many applications) promptness of signal, i.e., pulse shape.

Resolving Power. The resolving power depends on several parameters but chiefly on stochastic fluctuations in the number of charge carriers detected. The relative error in this number is larger, the fewer the charge carriers originally produced. It takes about 3 eV to generate a carrier pair in a *semiconductor.* Thus, if the 661 keV γ quantum emitted after the β decay of ^{137}Cs is absorbed in the semiconductor through the photoeffect

$$N = \frac{661 \times 10^3}{3} = 2.2 \times 10^5 \tag{4.5}$$

charge carriers are produced. The relative statistical error of this number is

$$\Delta N/N = \sqrt{N}/N = 0.21\ \%\ ;$$

if a normal distribution is assumed, the full width at half maximum (FWHM) of the line is about 0.5 % for semiconductor detectors.

With a *scintillation detector*, an energy of ca. 300 eV is required to expel an electron from the photocathode of the

multiplier tube (with allowance for light losses, etc.). Hence, the statistical uncertainty for the same line is $\Delta N/N$ = 2.1 %, corresponding to an FWHM of 5 %. The formation of an ion pair in a *proportional counter tube* takes ca. 30 eV, so that the line width calculated in a similar way would then be about 1.6 %. The fundamental limitations described here cannot be greatly improved by experimental technique, so these estimates are generally valid.

Efficiency. The detectors described up to this point have near 100 % efficiency for charged particles, provided the particles can enter the active volume. For γ radiation and neutrons, the detector efficiency depends on the density and atomic number of the detector material and its volume, as well as the energy of the radiation. Gas ionization detectors are not well-suited to detecting γ radiation except at extremely low energies, when xenon-filled proportional counters can be employed. The efficiency of a 3×3 inch sodium iodide detector located 60 mm away from the source is 4.5 % for 661 keV γ-rays, decreasing to ca. 3.5 % at 1.461 MeV (^{40}K). The proportion of events registered in the photopeak is only 45 % in the first case and 27 % in the second. The activity must be calculated from the area under this line.

Promptness of Signal. The time-domain properties of the pulses from these detector types may somewhat limit their use. Because the charge-carrier avalanche propagates throughout the tube volume, a Geiger – Müller counter has a long dead time and is thus poorly suited to the measurement of high pulse rates.

Short pulse rise time is important, along with pulse length, in coincidence applications. The behavior of the pulse over time may also depend on the type of particle detected or the place where it is absorbed in the detector; this information is also utilized in some applications.

4.2.2.5. *Integrating Detectors*

Besides the detectors described in the preceding sections, which are operated chiefly in on-line mode (signals interpreted as they are received), radiation can be detected by other methods.

It has long been known that ionizing radiation will blacken *photographic film.* The effect has been studied qualitatively and quantitatively and is highly reproducible; for these reasons, it is frequently utilized in official individual dosimetry. In order to gain information about the energy of γ and X-rays involved, the film is placed in a cassette with filters that attenuate the radiation in an energy-dependent fashion.

Ionizing radiation produces defects in special *glasses* so that part of the incident energy is permanently stored in the glass. If such a material is illuminated, it luminesces, i.e., emits light of a different wavelength than the incident light. The luminescent intensity is proportional to the irridiation dose previously received by the glass. The device using this effect, called the *photoluminescence dosimeter* (*PLD*), is distinguished by high long-term stability, low background, and low fading. The stored information about the dose can be erased by heating; optical reading does not affect the stored information.

In *thermoluminescence dosimeters* (*TLD*), the energy stored by radiation in a crystal, for example LiF, is emitted as light when the crystal is heated to 200 – 400 °C. The information is, however, erased when it is read out in this way; the information can be read only once. If the crystal is enriched with ^{6}Li, the dosimeter will be sensitive chiefly to neutrons because of the large (n, α) cross section of this nuclide; ^{7}Li-enriched crystals find use in γ dosimetry.

4.3. Measurement of Activity and Dose

As stated in Chapter Introduction, *activity* is always referred to a given nuclide or group of nuclides. If the nuclide is not known, it must be determined before an activity can be measured.

With a few exceptions, all radionuclides emit γ radiation after a decay event, and the γ spectrum can be used for nuclide determination.

The measurement of a *dose* or *dose rate* is generally referred to the photon dose rate, since (as discussed in Chap. The Biological Effects of Radiation and Radionuclides) this is the only form of external radiation — aside from the β skin dose — that can cause damage. In most countries, instruments for measuring the γ dose are subject to a calibration requirement; in Germany, only instruments of desaster response units are exempt from this requirement. On the other hand, no calibratable instruments are now available for the determination of the beta skin dose. This dose is derived from the measured activity per unit area.

4.3.1. *Gamma Spectroscopy for Radionuclide Determination*

Figure 26 shows a typical setup for high-resolution γ spectroscopy with a high-purity germanium detector. The detector and the preamplifier are mounted in a Dewar to keep them cold. Nowadays, the multichannel analyzer is usually replaced by an analog – digital converter connected to a personal computer, so that the spectrum can be plotted, the data can later be analyzed in the form of an energy and intensity calibration, and the activity can be determined from the results.

The spectrum in Figure 26 (curve b) shows the result of one such measurement. The resolution is higher than that of the sodium iodide detector (curve a); this gain is offset by a loss of detector efficiency and hence a much longer measurement time. Whereas the high-energy lines stand above a low continuous background, this background rises sharply at lower energies because of the Compton continuum of the higher-energy lines. The analysis of such complex spectra consumes a large amount of machine time. It involves fitting analytic functions to the lines, from high to low energies, determining the area enclosed, and calculating the Compton component.

Figure 26. Typical spectrum output by the system of Figure 25

Reproduced with the kind permission of [77].

a) NaI(Tl) detector, 3+5 inch; b) High-purity germanium detector

Manufacturers offer complete systems with extensive programs and libraries. On the basis of the energy calibration, these programs assign the lines to the respective radionuclides; using the intensity calibration and the known emission rate, they can also calculate the number of decays.

The result of the analysis is reported as the absolute activity of the specimen or may be converted to a specific activity (in, e.g., Bq/kg) or an activity concentration (in Bq/m^3).

If a high detector efficiency is required and the expected spectrum is less complex, so that less resolving power will be adequate, the energy, intensity, and thus the activity can also be measured with a sodium iodide scintillator. This detector is more robust and does not need to be cooled; what is more, the electronic hardware has a somewhat simpler design. The interpretation technique is, however, similar in principle to that employed with the HP – Ge detector.

4.3.2. *Other Methods of Radionuclide Determination*

For α *emitters that show no* γ *lines* or only at very low energies, the nuclide and its activity can also be determined on the basis of α spec-troscopy. The high energy loss of α radiation means, however, that a very thin specimen must be prepared so that the energy loss in the specimen will not interfere with the measurements. The specimen-to-detector distance must also be small, or the volume in between must be evacuated. The detectors employed are high-resolution silicon surface-barrier detectors or the easier-to-use plastic scintillators, though the latter do not offer the same resolving power as the semiconductors.

Since the detection efficiency for charged particles is close to 100 %; the minimal size of the detector is governed solely by the maximum range of the particles to ensure total energy absorption. The interpretation of the spectra is similar to that of the γ spectra, except that here the Compton background is not present.

The same detectors can also be used for *electrons.* Because β spectra are continuous, they cannot serve for nuclide identification unless a chemical separation has been performed first. If no γ spectrometer is available, then some of the radionuclides that decay by *electron capture*, such as ^{207}Bi, can be detected by conversion electron spectroscopy since the conversion electron spectrum is discrete. ^{207}Bi preparations are often used for the testing and calibration of particle detectors.

4.3.3. *Determination of Surface Activities*

In radionuclide laboratories, surfaces are often examined with hand-held probes using proportional counter tubes or plastic scintillators. In either case, the probe detects the charged particles but does not determine their energy, so that nuclide identification is not possible. The surface activity can be determined from the known detector efficiency and the known sensitive area of the detector, provided it is known what nuclide is responsible for the contamination.

Examples of contamination monitors employing counter tubes are shown in Figures 27 and 28 (left-hand instrument). The device in Figure 27 is an supplementary probe for use with series AD dose-rate meters (Automess, Germany) [75]. As in most modern hand-held meters, the digital display is controlled by a process control computer, which also performs functions such as count rate correction, averaging, timedomain integration, automatic range switching, and comparison with alarm thresholds. The instrument can distinguish between different types of radiation in the following way. The counter tube has an α-transparent window and is permanently gas-filled. If a low voltage range is selected, the counter tube is sensitive only to intensely ionizing α particles. At high counter tube voltages, where β and γ radiation is detected, β particles may be blocked by a steel plate (shown clamped to the detector) to measure the γ radiation alone.

Figure 27. Model AD-k large-area proportional counter (right) for contamination measurement, shown as an accessory to the AD-2 dose-rate meter [75]

The AD-2 can also be mounted directly on the AD-k

Figure 28. Contamat model FHT 111 M large-area proportional counter for contamination measurement (left); FH 40 F 1 dose-rate meter (center); FAG FH 41 F dose and dose-rate alarm (right) [78]

The instrument in Figure 28 [78] can use a permanently xenon-filled counter tube, which is suitable for detecting low-

energy γ radiation but has a thick window that blocks α particles. For α detection, a flow-through counter tube is used; this must be purged with butane or methane at regular intervals. α Radiation is identified by pulse shape allowing α and β radiation to be detected at the same time and displayed one after the other. The instrument offers functions similar to those just described. Calibration factors can also be programmed-in for various nuclides, permitting the direct display of a surface activity in Bq/cm^2. This figure will be correct only if the stated nuclide is actually responsible and, only if it is present in the form of a thin film on a smooth surface.

4.3.4. *Measurement of Photon Dose Rate*

A widely used instrument for measuring the photon equivalent dose *H* or photon equivalent dose rate $\dot{H}$ is the *Geiger – Müller tube*, which directly shows a dose rate in Sv/h, mSv/h, or even μSv/h. Modern instruments such as those shown in Figures 27 and 28 feature automatic range selection and can serve as front ends for other probes. Such a device can be supplemented by a high-dose counter tube on a telescoping arm for measurements in hot places or those with restricted accessibility.

Because of their long dead time, Geiger – Müller counters should be used with care when measuring high dose rates from pulsed radiation sources (accelerators, X-ray tubes). The manufacturer usually indicates the range in which reliable measurements are possible with pulsed sources. Geiger – Müller counters may give low readings on very low-energy γ radiation too; the permissible energy range is indicated with each instrument.

Dose-rate meters based on *ionization chambers* are free from these drawbacks but are less convenient and more fragile. Their sensitive electronics must be calibrated and checked more frequently, and the instruments are more costly.

In addition, *scintillation dose-rate meters* are on the market. They are similar to ionization chambers in operation and can be employed for measuring extremely low dose rates. Because of their complex design, they are delicate and require care in use.

4.3.5. *Area Monitoring and Personal Dosimetry*

International recommendations as applied in most countries require measurement of the dose to persons who work in controlled access areas. In most such facilities, the *dose* (*local dose*) or local dose rate at certain places must be measured and recorded, and alarms must be given if prescribed threshold values are exceeded. Moreover, many countries operate wide-area systems, especially around nuclear power plants, to monitor the dose rate. These fixed monitoring systems generally employ proportional or Geiger – Müller counter tubes.

In most cases, two independent dosimeters are used to measure the *personal* (*individual*) *dose;* one is read by the wearer, for example, at the end of a working day, whereas the second must be evaluated by designated agencies. Dosimetric films and PLDs are permitted for this use in many countries.

Pen dosimeters, the size of a fountain pen and incorporating an ionization chamber, used to be employed as self-readable dosimeters. An internal capacitor was charged to a certain voltage, which was also imposed on the wire of the ionization chamber. The charge carriers produced by radiation then discharged the capacitor. The decrease in voltage was directly readable on a built-in electrometer or an external instrument. Dosimeters of this type were not, however, very accurate; they had a high background and were also sensitive to external interference. Most of the personal dosimeters now on the market are based on Geiger – Müller tubes (Fig. 28). Miniaturization techniques make it possible to fit such a device into the volume of a fountain pen. A built-in microprocessor detects and counts the pulses from the tube, which can be output as a dose figure on an LCD display. Many instruments have an integrated dose-rate alarm, which beeps when a predetermined value is exceeded.

In certain operations, a *partial body dose*, for example, a hand dose, must also be determined. Small LiF crystals are employed as TLDs for this purpose; they can be worn as ring dosimeters or applied directly to the skin with tape. Depending on the ^7Li – ^6Li ratio, they can be applied to measure either the γ or neutron doses. The range of possible shapes for TLD crystals means that they have a wide variety of applications; automated readers are available (e.g., [82]).

Depending on their chemical form and metabolism, *incorporated radionuclides* can be detected by excretion analysis (e.g., ^3H in the urine). The activity of incorporated γ emitters can be measured with body counters (whole-body counters). Most such instruments feature large-volume scintillators, which make it possible to detect even low activities such as that of ^{137}Cs in the body.

A summary of monitoring techniques and instruments is given in Table 4.

Table 4. Summary of monitoring techniques and instruments

Method	Instrument	Application/detection of	Remarks
Counter tube	ionization chamber	photon dose rate/charged particles	also suitable for pulsed radiation sources
	proportional counter	contamination measurement, dose rate/charged particles, neutrons (BF_3 filling), low-energy photons (Xe filling)	moderate-resolution spectroscopy possible; particle discrimination possible
	Geiger –	dose-rate measurement	sturdy; no particle

	Müller counter		discrimination; caution when using with pulsed sources
Scintillator	organic (plastic) scintillator	dose-rate measurement/charged particles, neutrons	low resolution for spectroscopy
	NaI, CsI, BGO	gamma spectroscopy, body counter	high detector efficiency, low resolution
Semiconductor	SSBD	charged particles	high resolution; telescope for particle identification
	Ge(Li), HP – Ge	gamma spectroscopy	high resolution, low detector efficiency
Solid-state	film	dosimetry	official dosimeters
	PLD	dosimetry	high constancy, long-time measurements, official dosimeters
	TLD	^{6}LiF: neutron dosimetry	long-term constancy not so good;
		^{7}LiF: photon dosimetry	small, therefore good partial body dosimeters

5. Uses

Alfred Zyball, Andreas Gervé, Alexandru T. Balaban

5.1. Industrial Applications of Radionuclides

5.1.1. *Introduction*

The use of radiation in industry had its starting point in fundamental research in the 1940s and 1950s. The equipment used includes:

1. Electron accelerators with maximum energies up to 10 MeV
2. Gamma facilities with suitable radionuclides

The energy restriction arises from the process requirement that the irradiated products must not become activated. Thus nuclear reactions are not initiated in the products, nor are radioactive substances produced. The products can be utilized immediately after irradiation.

This chapter deals with the industrial applications of radionuclides (for application of electron accelerators, see ⟶ Radiation Chemistry). The γ radiation emitted by the radionuclides is utilized.

The output of *electron accelerators*, with energy ranges up to 10 MeV, is called “machine radiation” or particle radiation, because the electrons emitted by glowing cathodes are accelerated in a high-voltage field and used as radiation. In comparison, γ-*rays* have the advantage that their penetration is greater in the irradiated product than that of accelerated electrons.

The use of γ-rays enables the irradiation of larger units of products, such as products stacked on a pallet. Electron accelerator systems can only uniformly irradiate smaller units of specified size, such as single packages.

With regard to radiation protection, electron accelerators have the advantage that the radiation can be stopped by cutting off the power supply to the machine. Personnel can then enter the irradiation cell provided the ozone concentration is monitored. In a gamma facility the radiation can only be shielded but not turned off. This fact is crucial in site selection (earthquake hazard), in the design and construction of the equipment and safety systems, and in the organization of operation.

Work is now under way aimed at combining the advantages of γ irradiation (greater penetration) with those of the electron accelerator [85], [86]. If accelerated electrons strike a target, secondary radiation (bremsstrahlung or X-rays) is produced; this has a greater penetration which is dependent on the radiation energy. The research objective is to improve the efficiency of conver-sion and to study the energy spectrum of the secondary radiation with a view to industrial application.

5.1.2. *Radionuclides for Industrial Gamma Facilities*

About 1300 man-made radionuclides are known but only two of them account for virtually all industrial uses:

Cobalt-60 (^{60}Co)
Cesium-137 (^{137}Cs)

The more commonly used radionuclide, ^{60}Co, is generated in nuclear reactors when the stable isotope ^{59}Co captures thermal neutrons:

$^{59}Co(n,\gamma)^{60}Co$

^{60}Co is produced in reactors with thermal neutron fluxes of 10^{12} – 10^{15} n cm^{-2} s^{-1}. The conversion of ^{59}Co to ^{60}Co is 99 % [87]. The maximum specific activity produced is about 3.7×10^{13} Bq/g (1000 Ci/g). Commercial ^{60}Co sources take the form of rods with double metal cladding (Fig. 29). During fabrication, the metal capsules are leak-tested in order to prevent contamination in service. The individual ^{60}Co sources fabricated in this way generally have an activity of ca. 2×10^{14} – 6×10^{14} Bq (6 – 15 kCi). The activity of the strongest individual source is about 4×10^{15} Bq (10^5 Ci).

Figure 29. C-188 ^{60}Co radiation source at Nordion International Inc., Kanata, Ontario, Canada [88]

a) End cap; b) Body tube, *d* = 9.65 mm; c) Inner capsule; d) Spacer (as required); e) End cap

Around 1970, production of ^{60}Co was ca. 0.15×10^{18} Bq/a (4 MCi/a). A yearly output of 2×10^{18} – 3×10^{18} Bq (50 – 80 MCi) is exptected for the first part of the 1990s [89].

In 1991, 170 gamma-irradiation systems having a total activity of ca. 6×10^{18} Bq (150 MCi) were in use in 45 countries [90]. About 30 % of these systems are operated in service centers [91], [92].

Cobalt-60 Sources. Figure 30 shows a simplified decay scheme for ^{60}Co. The 314 keV β radiation is absorbed in the metal cladding around the ^{60}Co source and is not available for irradiation. The gamma quanta emitted by ^{60}Ni have energies of 1.173 MeV and 1.332 MeV; thus every decay results in the emission of two γ quanta with an average energy of 1.25 MeV. The half-life is 5.27 years (Table 5). The decline in activity is around one percent per month in practice. In industrial facilities, the source is generally in service for three half-lifes, i.e., 15 years. After this time, the source is either installed in a facility which requires irradiation with only a small activity, or it may be disposed of in the same way as radioactive waste from nuclear power plants. After ca. 200 years, by virtue of the short half-life, the activity will have decayed to a point where radiation exposure due to the source is at the natural background level.

Table 5. Characteristics of the radionuclides ^{60}Co and ^{137}Cs [93], [94]

Radionuclide	^{60}Co	^{137}Cs
Form	Metal (solid)	CsCl (water-soluble)
Half-life, a	5.27	30.17
Decrease in activity per year, %	12.39	2.28
γ energy, MeV	1.173 (1.0)	0.662 (0.858)
(emission probability)	1.337 (1.0)	
Half-value layer in water, mm	110	70
Self-absorption of energy, %	≈ 10	≈ 30
Radiation power, kW/10^{16} Bq (kW/MCi)	4.01 (14.84)	0.90 (3.32)

Figure 30. Simplified decay of ^{60}Co

Cesium-137 Sources. ^{137}Cs originates as a fission product of ^{235}U in nuclear reactors. In industrial irradiation systems, it is used in encapsulated form as the sulfate, cesium glass, or often as the chloride. According to [93], ^{137}Cs is one of the most abundant fission products of ^{235}U (55 % of waste radioactivity, 50 % of energy content). The amount of ^{137}Cs produced by nuclear reactors in the United States in 1987 was reported to be 3.5×10^{18} Bq (90 MCi). Despite the availability of this high activity, ^{137}Cs is seldom used in industrial gamma facilities. The reasons are the low energy of 0.662 MeV and the long half-life of the nuclide (see Fig. 31 and Table 6). The low energy of the emitted γ-rays also means that self-absorption of the radiation in the cladding of the radioactive material is high (30 –50 %). Even though the activity is high, the output of a ^{137}Cs gamma equipment is low. The most frequent application of ^{137}Cs is in pilot plants for the disinfection treatment of sludge [94].

Figure 31. Simplified decay of ^{137}Cs

5.1.3. *Design of Gamma Equipment*

The initial planning of an irradiation facility that will utilize radionuclide sources must deal with two fundamental problems:

1. How to design the irradiation equipment so as to ensure safe operation, especially in compliance with radiation safety regulations
2. How to design and lay out the entire equipment in order to achieve a technically and economically optimal handling of the product to be irradiated

An industrial irradiation system includes the following basic devices (Fig. 32).

Figure 32. Gamma facility for irradiation of products on pallets

a) ^{60}Co sources; b) Water basin; c) Shipping packages; d) Entrance labyrinth; e) Exit labyrinth; f) Water treatment; g) Control room; h) Concrete shielding

Radiation Source. Sources are available in point, line, plate, or cylindrical shape; cylinders and plates being the most common (Fig. 32). In every source the source rods (Fig. 29) are assembled in such a way that the radiation field produced in the irradiation cell complies with the requirements on the irradiated product. The positions of the rods in the radiation source are calculated by computer.

Radiation Shielding. Shielding and other types of radiation safety equipment must be designed to enable safe operation and to prevent the radiation source from endangering the plant personnel or the environment. For this reason, the radiation source is enclosed in concrete walls that are 1.5 – 3.0 m thick. The walls and the labyrinth through which the product is conveyed must be designed so that the dose rate outside the irradiation cell (monitored area of the plant) is < 2.5 μSv/h (0.25 mrem/h).

Source Storage. The radiation source can be safely stored when personnel have to carry out necessary maintenance and repairs or when source rods need be replaced or repositioned inside the source. For storage purposes, the irradiation source can either be completely submerged in water to permit safe entry into the cell or in some plants, the source is securely stored by means of a radiation-proof cover (dry storage) [95].

Conveyor System. The conveyor system transports the product into the cell for irradiation and places it in the correct irradiation positions. Both functions must be efficiently carried out as the effect produced by irradiation in the product is largely dependent on them.

Ventilation System. The cell has a forced-air ventilation system to remove gases produced during irradiation (e.g., ozone, nitrogen oxides).

Cooling System. Because most systems built today have high activities (45×10^{18} Bq, i.e., 12 MCi), the source storage facility must be cooled. The irradiation cell itself must also be cooled in plants handling frozen products.

Monitoring and Control System. The first task of the monitoring system is radiation protection; this equipment ensures that the specified local dose rates are not exceeded; unauthorized access to the irradiation cell is prevented until the radiation source has reached its final position in storage; and that contamination does not occur as a result of any leakage from the source rods. The control system, which employs a microprocessor in new plants, monitors, controls, and documents the irradiation process.

Storage Facilities. Product storage facilities are associated with any industrial irradiation system. In order to clearly distinguish irradiated and nonirradiated products in the storage area, the two are stored separately.

5.1.4. *Irradiation Using Gamma Rays*

The changes in the product properties that occur during irradiation depend to some degree on the energy dose and are also influenced by the dose rate. The dose rate becomes a factor, however, only when a product is irradiated with a high-dose-rate electron accelerator rather than a low-dose-rate gamma system.

Achieving specified changes requires delivering a *minimum dose* to the product; there is also a *maximum dose* that must

not be exceeded in order to prevent undesirable damage to the product. For a product with homogeneous density, the *absorption* of radiation and thus the dose exponential relationship (Fig. 33). The shape of the curve is determined by the density of the absorbing material. As the figure shows, products are often irradiated from at least two sides in order to optimize the maximum/minimum ratio.

Figure 33. Dose distribution after irradiation from one and two sides

A and B positions of source relative to product

a) Dose distribution after irradiation from position A; b) Dose distribution after irradiation from position B; a + b) Resulting dose after irradiation from two sides

D_{max} = maximum dose; D_{min} = minimum dose; *S* = source; a + b=total dose

The following questions must be answered in the development of a facility.

1. What products will be irradiated in the gamma facility, and in what state will they be?
2. What are the minimum doses? What maximum values must not be exceeded?
3. What are the nominal doses for product irradiation?
4. What equipment efficiency is possible given the above requirements?

If granular or free-flowing products are irradiated in a system, 100 % efficiency is possible, because the product can be configured in accordance with the spatial pattern of γ emission from the radiation source.

The product to be irradiated is supplied in containers, cartons, or other packaging units and is transported past the radiation source by conveying systems. The efficiency of such installations is < 40 %. In the past, a number of concepts were devised and designed with the objective of improving the efficiency. The essential requirement is to surround the radiation source with products so that they correspond to the spatial γ emission pattern.

A few concepts are described in Figure 34. Further information can be found in [96-104]. Figure 34 A shows a cylindrical source with eight irradiation positions. The concept illustrated in Figure 34 B has four irradiation positions around the cylindrical source; the product must be irradiated in at least two configurations to ensure homogeneity of dose. Figure 34 C shows a plate-type source with ten irradiation positions. Again, the product must pass through different positions.

Figure 34. Configuration of sources relative to product

A) Cylindrical source with 8 irradiation positions; B) Cylindrical source with 4 irradiation positions; C) Plate-type source with 10 irradiation positions; D) Source overlapping product; E) Product overlapping source

Basic arrangements of radiation source and product are shown in Figure 34 D and 5.6 E. In Figure 34 D, the radiation source overlaps the product. This results in a homogeneous dose distribution but the efficiency is poor. The arrangement in Figure 34 E offers an optimized efficiency. The product overlaps the source. A complicated handling system is required in the irradiation cell to obtain optimal dose distribution.

A gamma facility should also exhibit flexibility or versatility. The unit must be able to irradiate products that vary in density (with specified maximum/minimum dose ratios), and it must deliver a range of doses with no loss of efficiency. There are two possibilities: First, the maximum/minimum ratio can be improved by reducing the irradiation depth. The dose distribution for a constant density is determined by the depth of the product in the irradiation direction (see Fig. 34). The key parameter for the maximum/minimum ratio is the product of density and size of the product. The depth of dose distribution is often referred to as the mass or weight per unit area.

The second possibility is to apply the total dose step by step, using an appropriately designed conveyor system inside the irradiation source. The total dose is then a multiple of the dose that the product absorbs while passing through the cell once.

5.1.5. *Uses of Irradiation*

Industrial applications of irradiation with radionuclides include:

1. Disinfection – sterilization
2. Modification of plastics (cross-linking – degradation)

5.1.5.1. *Disinfection – Sterilization*

Excited molecules, ions, and/or free radicals are formed in an irradiated product as a result of energy absorption. In living cells, e.g., microorganisms, this energy absorption leads to defects in the DNA. A repair mechanism for DNA exists, but if the number of defects highly exceeds the DNA repair capability, the microorganism will die. The rate of destruction is an

exponential relationship of dose if other environmental conditions remain constant. It is possible, therefore, if the microbial contamination of the product is known, to determine what dose is necessary to achieve an acceptable population level of microorganisms or to obtain a sterile product.

“Sterile” products are required in the medical field. Although this term is defined as “free of any microbial forms capable of reproducing, and also of viruses and bacterial spores,” all that is possible is a probabilistic statement of the product condition. Most countries therefore consider a product sterile if there is less than a 10^{-6} probability that a single viable microorganism is present.

The history of radiation sterilization since the 1950s has been described [105]. Intensive research on the resistance and inactivation of microorganisms has led to the recognition that a product fabricated in compliance with good manufacturing practise (GMP) standards and irradiated with a dose of 25 kGy is sterile as defined above. Because irradiation may also change the properties of the product or its packaging, statistical procedures have been devised so that products can be irradiated with doses of less than 25 kGy and still be reliably sterilized at the 10^{-6} level [106].

Radiation sterilization is employed with products that are thermolabile and thus cannot be sterilized with superheated steam. These include products made from plastics. Radiation sterilization offers other advantages in this area:

1. The product is sterilized in the final packaging, so there is no danger of subsequent recontamination.
2. The product can be utilized immediately after sterilization.
3. The sterilization process is easy to monitor. The destruction rate of the microorganisms depends on the radiation dose, a physically measurable quantity. The duration of the product in the irradiation equipment is the deciding factor in this process.
4. Radiation sterilization is no more expensive than sterilization with ethylene oxide (⟶ Ethylene Oxide – Uses). It may even be less expensive if safety standards and regulations in gas sterilization with ethylene oxide are taken into account.

About 95 % of installed ^{60}Co activity in 1990, i.e., 90 % of the total volumetric radiation capacity was utilized for the radiation sterilization of medical devices. Thus, in 1990, 45 % of medical devices were being sterilized with radiation instead of ethylene oxide; in 1977 this fraction was a mere 5 % [107].

The second most important application of irradiation with radionuclides is the treatment of food products (⟶ Radiation Chemistry – Regulations on the Irradiation of Foods and Feeds, ⟶ Radiation Chemistry – Industrial Irradiation of Foods and Feeds). In 1990, 29 gamma facilities were in service in 22 countries for this purpose [108]. Projections for the early 1990s are that 55 units will be in operation. Irradiation of food has been heavily promoted by the FAO, IAEA, and WHO. In 1980, an expert committee concluded that food irradiated up to an overall absorbed dose of 10 kGy, presents no toxicological hazard and introduces no special nutritional or microbiological problems [109].

The goals of food irradiation are improved shelf life, sterilization, decontamination, disinfestation, insect control, and delayed ripening.

Other applications of irradiation sterilization include the following:

Packaging Industry. Packaging for beverages, milk products, pharmaceuticals, or cosmetics must be sterile in order to prevent contamination of the products.

Pharmaceutical and Cosmetics Industries. Irradiation can be employed to sterilize either the raw material or the end product.

Sludge and Wastewater Treatment. Clarifier sludge containing no heavy metals or toxic chemicals can be utilized as an organic fertilizer, provided no pathogens are present. This can be ensured by irradiation. A few plants using this technology have already been in operation in various countries. Studies are now being performed to determine to what extent wastes generated in airports, seaports, and hospitals can be irradiated before downstream treatment.

Treatment of Wood. The purpose of irradiating wood is to kill harmful organisms that might cause major damage if exported to other regions.

5.1.5.2. *Modification of Plastics (see also ⟶ Radiation Chemistry)*

The following reactions can be initiated by irradiation of plastics:

1. Cross-linking
2. Degradation
3. Grafting

These reactions are generally accomplished by irradiating products in electron accelerators and have led to a number of improvements in materials as well as new applications for plastics. *Cross-linking* improves the mechanical, chemical, and thermal properties of a plastic. Areas of application include, e.g., the cable industry, the manufacturing of pipes (plastic pipes for floor heating and hot water supply systems), and shrinkable products. *Degradation* (reduction in molecular mass) is employed in order to produce low-molecular-mass polytetrafluoroethylene (for use as a lubricant or dye additive) and polypropylene (as a seeding agent for crystallization of injection-molded articles). This technology is occasionally used in industry for the grafting of plastics to fabricate membranes or fibers with well-defined properties.

These technologies are being adapted to permit irradiation in gamma facilities because the greater penetration of ϒ-rays enables irradiation even of large plastic components at low cost. The results achieved with an electron accelerator cannot be simply extended to the gamma facility, because the latter features a dose rate several orders of magnitude lower. The radicals produced in the irradiated products prefer to react with oxygen. If the irradiation occurs in low dose rates, atmospheric oxygen diffuses into the irradiated product (paricularly at and near the surface) and other processes, e.g., oxidation can occur. Plastic components irradiated in a gamma system therefore still require testing.

5.1.6. *Wear Measurement with Radionuclides [110]*

The use of radionuclides for wear measurement is an important tool for improving tribological systems. This technique offers the following advantages:

1. Continuous measurement of wear versus time on machine parts in service
2. Correlation of wear performance with operating conditions
3. High sensitivity
4. Problem-oriented selection and definition of wear regions for study
5. No interference with operating conditions or with the material of the machine part under study
6. Cost savings
7. Time savings over conventional methods

Continuous wear measurement with radionuclides comprises two methods; the differential method and the concentration method. Each permits continuous observation of the progress of wear without having to stop or disassemble the machine. The time dependence of wear is determined from the radiation emitted by the radioactive material.

Differential Method [111], [112]. In the differential or thin-layer differential method, the condition of a wearing part is ascertained by activating a thin layer of the part's surface and measuring its residual activity. During the trial, a probe comprising a detector and an integrated amplifier monitors a tribological system through the housing wall, measuring the decline in radioactivity remaining on the part and thus the increase in wear. The sensitivity of this form of wear measurement is ca. 10 nm/h.

Thin-layer activation of machine parts is performed with charged particles (e.g., protons, deuterons, α particles) in an accelerator such as a cyclotron [113], [114].

The thin-layer activation technique yields regions of constant activity between 20 and 500 μm. The total activity of the machine part is ca. 370 kBq.

Solving a tribological problem entails converting tribological data (material composition, sensitivity required, test duration, etc.) into activation data (type of bombarding particle, irradiation angle and time, etc.).

Generally, sodium iodide detectors are employed with electronic output coupling to obtain high counting rates. The count pulses can be recorded and classified and converted to wear values (e.g., in nm or μg) with a wear meter; this instrument is easy to operate without special knowledge of nuclear physics and radiometry.

These measurement data must be converted to tribological data, which requires adequate knowledge not only of radionuclide techniques but also of tribology.

Concentration Method [112], [114]. The concentration method involves measuring wear by detecting the radioactivity of the activated wear particles carried away by a medium. The transporting medium can be, for example, a lubricant or a fuel that flushes the wear particles from the activated part, such as oil in an internal-combustion engine. The medium and wear particles are conveyed to a highly sensitive probe, which measures the activity concentration. The wear probe determines the numerical activity values. From this, the volume of carrier medium, the activity per unit mass, and the half-life of the radionuclide can also be calculated. The instrument calculates the wear values and outputs them, in, for example, nm or μg. The concentration method again requires a radioactivity of ca. 370 kBq in the machine part.

The transport medium can be brought to the measuring probe either as discrete samples or in a continuous fashion. With gamma spectrometry, several wear components can be measured simultaneously [115]. Sodium iodide detectors are advantageously used in the concentration method as well.

The concentration method offers higher accuracy and sensitivity than the differential technique (in the nm/h range in typical applications).

If filters are located in the circulation loop of the transport medium, the continuous-flow method can be supplemented by a filter probe. Such a wear measuring system thus determines wear particles in the filter, wear particles not retained on the filter, and total wear.

Uses [116-120]. Radionuclide methods of wear measurement can be used to analyze the wear behavior of tribological systems. The results (wear as a function of the operating conditions of the machine or system under study) can aid in optimizing material pairs, design (macroscopic and microscopic form of wearing partners), lubrication, and operation in tribological systems. Another important aspect is the measurement of the anti-wear actions of various lubricants in order to optimize tribological systems. Radionuclide-based techniques can also be used for corrosion measurements.

Radionuclide methods are especially suitable for wear analysis on *internal-combustion engine parts.* Parts that have been examined in the running motor include: piston ring, cylinder liner, piston, piston ring groove, main bearing, connecting-rod bearing, crankshaft, valve seat, valve seat rings, valve stem guide, rocker arm, camshaft, cam follower, and chain wheel.

Other suitable applications include *drive-train technology* (wear of gears, roller bearings, free-wheels, steering joints), *railroad engineering* (wheel and rail wear), *pumps* (cavitation at pump impellers), and *machining* (tool wear). Radionuclides find use for wear measurement chiefly in research and development departments of automobile producers and in research institutes.

The highly sensitive continuous techniques described here yield on-line results. Extensive new information can thus be obtained on the wear behavior of tribosystems and the anti-wear performance of lubricants and additives. Only these wear measurement methods allow practical wear problems to be solved more quickly and completely; only with these can significant advances be achieved in wear research.

5.1.7. *Other Industrial Applications of Radionuclides [121], [122]*

In the *iron* and *steel industries*, radioisotopes are used for level gauges to control the feed of blast furnaces. Radioactive sources at various depths in the refractory brick walls of blast furnaces monitor the rate of refractory disappearance.

In the *aluminum industry*, the flow of material in the dissolution of bauxite in aqueous sodium hydroxide can be monitored by ^{32}P or ^{59}Fe labeling of particles. During the dehydration stage in the production of alumina, residence times in the fluidized-bed reactor can be measured by similar labeling. The movement of molten aluminum in the electrolytic reduction cells can be followed with titanium capsules containing a radioactive isotope.

In the manufacture of finished *basic metal products*, autoradiography gives an image of the distribution of various radioelements and of the crystallization process in metals.

Radioisotope Applications in Dairy Technology. These applications include automation gauges with ^{90}Sr or ^{137}Cs for filling containers with predetermined volumes of milk, cheese, etc. Also, milk fermentation and cheese ripening have been followed by ^{14}C- and ^{35}S-labeling of saccharides and methionine, respectively. Neutron activation allows the detection of several antibiotics in milk, which may have been administered to cattle, while dosimetry of milk and dairy products can detect harmful radionuclides originating from fall-out or nuclear events such as the Chernobyl accident.

Applications of Radionuclides in the Chemical Industry. The main *applications of* γ *radiation* are described in Sections Uses of Irradiation and Wear Measurement with Radionuclides and in ⟶ Radiation Chemistry.

In addition, radionuclides are used in the disinfection of solid waste, sewage sludge, and polluted water.

Near Munich, a plant treated 1000 m^3 of wastewater per day with ^{60}Co γ radiation for destroying disease-carrying microorganisms. Disinfected water was subsequently applied to farmland.

Applications of *sealed sources* are based mainly on the exponential attenuation of γ-rays. When the density and composition of the medium to be investigated remain constant, its thickness can be determined (e.g., coke deposition in cracking furnaces, or corrosion of pipes). When the distance between the sealed emitter and the detector is constant, the density or composition of the medium can be determined and monitored continuously. For instance, the height of a foam layer in a chemical reactor, the efficiency of a demister, or the amount of carry-over of liquid droplets can be determined as a function of reactor conditions. For packed columns, the presence of voids in catalyst beds can be identified. Density profiling of distillation columns may be carried out routinely for determining faults such as flooding, foaming, or missing or collapsed trays. *Gamma ray back-scattering* can be used for thickness and coating measurements or for detecting build-up of deposits inside reactor walls, boilers, or condenser water boxes.

Neutron source applications include moisture measurements, elemental analysis, and determination of the position of interfaces between immiscible liquids. The best sources for fast neutrons are ^{241}Am – Be.

For *radioactive tracer applications*, the tracer can be in a chemically identical form to the material under study (intrinsic isotopic label), or in a chemically different one: either an isotope of an element present in the material is used or a foreign radionuclide (extrinsic label). The most important tracer application is on-line flow rate measurement for liquids or gases. It is possible to precisely calibrate flow meters, to identify leakages, and to quantify leakage rates. For improved radiological safety, short-lived radionuclides from radioisotope generators are preferably used, e.g., the ^{137}Cs – ^{137m}Ba generator (the half-life of ^{137m}Ba is 2.6 min). Mean residence times and residence-time distributions of materials in full-scale process vessels can be measured. For leak detection in gaseous separation systems, ^{41}Ar can be used; for similar purposes in liquid systems ^{82}Br in a suitable chemical form can be employed.

Gross liquid droplet entrainment can be monitored by γ-ray absorption techniques. For detecting *minor carry-over* (the elimination of which considerably improves the operating conditions), tracer techniques can be used; thus in distillation columns, droplet entrainment is quantitatively measured by injecting a nonvolatile radiolabeled component (e.g., manganese-56 naphthenate) into the feed of the column and by assaying its content in the gaseous overheads stream.

Activable tracers (⟶) can be used when radioactive tracers are not allowed because of safety reasons, or because a radioactive label would interfere with existing radioactive gauges. Unlike other methods which can detect minute amounts of materials (such as dyes, fluorescent compounds, or bacteria), activable elements hardly contaminate the materials and are innocuous before activation; only a small sample is activated. The only drawback is the necessity of using a nuclear reactor.

Some activated elements have a very low limit of detection: it is 10 pg for Eu and Dy, 50 pg for In and Mn, 100 pg for V, Au, Lu, Ho, Ir, 1 ng for I, and 5 ng for Co. For instance, if a leak is suspected in a factory drainage system, any or each of the above elements can be introduced in a suitable chemical form (chelates for the metallic cations, iodide anion for

iodine) into possible sites, and after a certain time samples are taken, activated in a nuclear reactor, and monitored with a multichannel γ analyzer. Neutron activation analysis can also be employed for determining the efficiency of full scale mixing units such as polymer chip blenders or of grinding devices.

5.2. Uses in Hydrology

There are three main techniques for using isotopes and radiation in hydrological studies: (1) Use of natural isotopes; (2) of artificial isotope tracers; and (3) of sealed radiation sources. Table 6 shows some natural radioisotopes of hydrological use.

Table 6. Natural radioisotopes of hydrological use [123]

Nuclide	Half-life	Residence time	Hydrogeological applications
^{3}H	12.3 a	1 – 40	travel time
^{14}C	5770 a	500 – 50 000	origin of carbon compounds
^{36}Cl	3.10^{5} a	$5\times10^{4} – 2\times10^{6}$	infiltration rates after the 1960s
^{222}Rn	3.8 a		presence of groundwater in subsurface water
^{226}Ra	1622 a		tracing water origin

In most cases, radioactivity measurements are simple to perform and can be conducted using portable instruments, unlike measurements of isotopic abundance for stable isotopes (⟶ Isotopes, Natural – Isotope Effects in Nature).

5.2.1. *Snow and Ice*

For dating ice in glaciers, natural radioisotopes with a medium half-life such as tritium or ^{210}Pb can be used when the ice is up to 100 years old; for ice of 100 – 500 years of age, ^{32}Si is suitable and for even older ice only ^{14}C is applicable. Tritium has the drawback that its concentration on earth has increased considerably after 1952, and that contamination with atmospheric water vapor must be completely avoided. ^{14}C also needs exclusion of contact with the atmosphere, and requires correction factors.

Since about 80 % of all land fresh water on earth exists as ice and snow (most of which is concentrated in the polar regions and in glaciers), assessment of global water balance and turnover must consider this ice – snow cover. The density of this cover varies with depth and various local conditions. Nuclear techniques for measuring this *density* use the exponential attenuation of γ radiation emitted by artificial radioisotopes in sealed radiation sources (^{60}Co, ^{90}Sr, or ^{137}Cs) each with characteristic γ energies:

$$\ln(I_0/I) = \mu d$$

where I_0 and I are the intensities of incident and attenuated γ radiations, μ is the linear absorption coefficient of water for the corresponding γ energy, and d is the distance from the γ emitter which is located at a certain depth in the ice pack to the detector. A bore is drilled into the ice thus securing a place for the γ-ray source. The amount of snow deposited in winter time is measured using a ^{60}Co source which is placed on the soil in summer. A detector is placed at a known distance (a few metres) above the ground. During the winter the amount of snow (or snow-containing water at temperatures around 0 °C) between the γ-ray source and the detector can be determined. Similar devices have been used for measuring soil moisture.

5.2.2. *Transient Surface Water*

For measuring the flow rate of a water course, a tracer can be injected at some point and its concentration measured at a point sufficiently far downstream (0.2 – 2 km) for complete lateral mixing to have occurred. The point should not be too close as then mixing would be incomplete, and not too far otherwise excessive dispersion and adsorption on the river bed occurs. Unlike nonisotope tracers (such as dichromate, chloride, sulfate, or nitrite anions, and rhodamine or other dyes which may undergo chemical reactions within the river, especially in the presence of pollutants), isotopic methods are usually safe from such sources of error. Tritiated water is also error-free with respect to adsorption on the river bed or suspended particles, but measurement of the emitted radiation requires more sophisticated equipment than that required for γ emitters, and its half-life is longer than that of radioisotopes such as ^{24}Na, ^{82}Br, ^{32}P, ^{123}I, ^{131}I, and ^{198}Au. Therefore, ease of measurement, accuracy of results, and safety considerations should always be taken into account when selecting the tracer.

There are two main techniques for such measurements:

Constant-Rate Injection Method. Here a tracer with a certain concentration c_0 is injected at a constant rate q into a watercourse with a flow rate Q. By measuring the concentration c after mixing is complete (when c becomes constant downstream) the flow rate can be determined as :

$$Q = q\,c_0/c$$

.

Integration Method. This method makes use of an instantaneous injection of a tracer with activity A_0 into a watercourse. After the mixing distance, the passage of the radioactive cloud is measured at a constant rate over a period, and the mean concentration C is obtained by integration; hence

$$Q = A_0/Ct = A_0V/At,$$

where A is the activity of the sample with volume V.

Most measurements are performed with ^{82}Br which has a large permissible dose in drinking water, or with ^{198}Au, and the activity is determined with scintillation detectors [124], [125].

When using *tritiated water* (HTO) the integration technique is preferred. An ampoule with HTO is crushed under water to avoid contamination: activities of about 150 – 200 GBq must be used for a flow rate of 100 m^3/s. For flow rates larger than 200 m^3/s and velocities in excess of 5 m/s, only radioactive tracers give reliable results [126].

In order to measure transit times for direct surface run-off in hydrological basins, similar techniques can be applied by injecting instantaneously a radiotracer (either as anions such as $^{82}Br^-$ or $^{131}I^-$, or chelates such as $^{51}Cr^{3+}$ – EDTA).

5.2.3. *Lakes and Reservoirs*

The dynamics of water flow, i.e., horizontal or vertical circulation, can be estimated either by using natural isotopic tracers (stable isotopes HDO or $H_2^{18}O$, or radioisotopes HTO, $^{14}CO_2$, ^{222}Rn), or artificial radionuclides. These are either anions such as $^{82}Br^-$, $^{131}I^-$, $^{60}Co(CN)_6^{3-}$, $^{51}CrO_4^{2-}$, $^{198}AuCl_4^-$, or EDTA chelates of transition-metal cations such as ^{46}Sc, ^{51}Cr, or ^{140}La. The radioactivity measurement is performed at various distances, depths, and times from the point where the artificial radiotracer was introduced.

Lake Constance was shown, by means of tritium monitoring, to undergo complete mixing in late winter and spring, whereas in summer its water is layered, these studies were complemented by the monitoring of ^{222}Rn in equilibrium with ^{226}Ra [127].

Leakage of water from reservoirs can be monitored by natural tracers or artificial radionuclides as tracers such as the anions $^{51}CrO_4^{2-}$, $^{82}Br^-$, $^{131}I^-$ or $^{198}AuCl_4^-$. If a higher sensitivity of measurement is necessary, the chelate ^{51}Cr – EDTA can be used which is retained on percolation through active carbon. This facilitates the measurement of very dilute solutions, so that 0.4 GBq of ^{51}Cr can be used for labeling 1×10^6 m^3 water [128].

Vertical or horizontal movements of water in the soil can be traced by injecting tritiated water when little interference of adsorption by soil constituents arises.

When, owing to government regulatory restrictions or to proximity of public or private drinking water supplies, it is not possible to use radioisotopes for tracing the movement of groundwater, neutron activation analysis with a nontoxic neutron-activable element can alternatively be used. The most suitable is ^{79}Br (50 % natural abundance in natural bromine) as bromide anion. By the nuclear reaction (in a nuclear reactor) ^{79}Br (n, γ) ^{80}Br, ^{80}Br with a half-life of 17.6 min is formed whose detection limit is below 1 ppb; in fresh water the typical background concentration is 10 – 100 ppb. For deep groundwater,iodide is the most suitable acturable anion, having very low background concentrations.

For localization of leakage sites in large water reservoirs, a radioactive tracer such as ^{198}Au or ^{113m}In (from a ^{113}Sn – ^{113m}In radioisotope generator) is introduced in the form of a ribbon-like cloud at a constant distance from the bottom of the reservoir (activity about 10 MBq per meter length of the investigated section). When a leak is present, the vertical component of the water flow draws radioactivity to the bottom where it is adsorbed on the bottom surface. After a certain time (e.g., 1 h), an assembly of scintillation detectors with a buoy marker is swept over the bottom; the radioactivity profile over the strip then allows to detect the sites of leaks [129-131].

Ground water in aquifers and underground water can be monitored using natural stable isotopes (^2H and ^{18}O) or radioisotopes (HTO and $^{14}CO_2$). ^{14}C needs corrections for the dilution. Measurements of the radioactive $^{14}CO_2$ content in water trace the contact of the latter with atmosphere, because limestone is practically ^{14}C-free owing to its very old age [132].

By means of natural isotopes (both stable, and radioactive, namely ^3H and ^{14}C) the age of deep aquifers in Western Roumania could be established to be around 30 000 a; in South-East Roumania (between the Danube and the Black Sea), isochronic curves revealed the important part played by recent tectonics, which give rise to conditions for an active, upward exchange of water from deep aquifers [133-136].

5.2.4. *Sediments in Hydrology*

Sediment Movement in Rivers and Estuaries. For labeling sediment, it can be mixed either with a radioactive glass (containing Ta, Sc, La, Ir, or Au, and activated in a nuclear reactor) crushed to a satisfactory particle size, or with a radioisotope-charged exchange resin. Alternatively, sand that is surface-labeled with a radioisotope can be applied. Sand used for the study of sediment movement in Botany Bay (Australia) was surface-labeled with $^{51}Cr_2O_3$ by immersing it under stirring in an ammonium [^{51}Cr]dichromate solution which was evaporated to dryness and then heated at 350 °C for 30 min [137]. Other radioisotopes frequently used for sand labeling are ^{46}Sc, ^{192}Ir, and ^{198}Au [138].

When building dams, it is important to estimate future sedimentation conditions. By γ-ray scattering, the density of sediments can be measured at the bottom of lakes and reservoirs to depths of 6 – 12 m (less for sandy sediments), and to water depths of about 100 m. In Lake Mead (United States), a sealed ^{60}Co source was used for the sediment density measurement.

Harbor construction and enlargement works need to choose dumping areas for dredged material, i.e., to take into account the global movement of sediments. The labeled particles representative of natural sediments are mixed with dredged materials [139].

Suspended sediment flows much faster than the sediment deposited along the bed of the river. Conventional determination methods (filtration or centrifugation, followed by weighing the solids) perturb the flow and cannot be performed continuously. By using a sealed γ source such as ^{109}Cd (γ energy: 22 keV) or ^{241}Am (60 keV) the attentuation caused by the suspended particles can be monitored continuously.

5.3. Uses in Agriculture

The main elements of agricultural interest are carbon, hydrogen, oxygen, nitrogen, and phosphorus. Radiotracers for some of these elements are ^{14}C, ^{3}H, and ^{32}P. Oxygen and nitrogen radioisotopes are very short-lived, therefore stable oxygen (^{18}O) and nitrogen (^{15}N) isotopes are preferred. From the metallic elements, ^{22}Na and ^{45}Ca are also useful in agrochemical studies, but ^{42}K and ^{43}K are too short-lived, and ^{40}K too long-lived (specific activity too low), so that sometimes ^{86}Rb is used as a foreign (extrinsic, or nonisotopic) tracer for potassium.

For determining the ion exchange capacity of soils, $^{36}Cl^{-}$, $^{45}Ca^{2+}$, $^{23}Na^{+}$, or other radioactive cations or anions are used. Weighed amounts of soil are treated with known volumes of radionuclide solutions with calibrated concentration, and after separation by centrifugation, the radioactivity of the supernatant is measured for determining how much radionuclide has been removed by adsorption onto the soil.

The adsorption and movement of phosphate anions (from apatite, superphosphate, or other phosphatic fertilizers) differ markedly from those of other anions. ^{32}P-Labeled superphosphate has been used for determining the optimum depth and timing for applying the phosphate fertilizer as a function of the soil pH [140]. Isotope dilution analysis can be used for determining the amount of phosphate and its adsorption by the soil, using ^{32}P or ^{33}P. The uptake of sulfate and phosphate anions can be easily traced using $^{35}SO_4^{2-}$ and $^{32}PO_4^{3-}$, respectively.

Microelements in the soil can be traced by means of corresponding radionuclides, such as ^{54}Mn, ^{58}Co, ^{60}Co, ^{59}Fe, ^{64}Cu, and ^{65}Zn [141].

Studies on photosynthesis use $^{14}CO_2$ in a confined atmosphere and blue-green algae, cyanobacteria, or halobacteria, and give information on the fate of energy transfer from photons at various extremely short times in the photosynthetic chain.

Similarly, biosyntheses of terpenoids, vitamins, antibiotics, and other phytosynthetic products can be elucidated by using isotopically-labeled precursors (preferably ^{14}C and ^{3}H).

Deforestation occurs as the world population increases, claiming agricultural areas and wood for burning or for building homes. The conversion of forested areas into agricultural land is as old as civilization, but studies on the formation of fertile soil from plant residues, as well as of soil humic constituents, are fairly recent. With ^{14}C-labeled plant material it was possible to monitor the mineralization to humin and humic or fulvic acids in the presence of mycoflora (cellulolytic fungi) [142], [143].

5.4. Uses in Environmental Studies

Agrochemicals, e.g., fertilizers, pesticides (insecticides, herbicides, fungicides, rodenticides, etc.) can pose serious threats to the environment when they are not used rationally. In many countries, it is mandatory to study the fate of agrochemicals when they are registered at a government regulatory agency (e.g., EPA in the United States).

Isotopically-labeled compounds (in many cases the tracer is ^{14}C) are used for following the fate of agrochemicals and of their chemical or biochemical degradation products. The following studies are normally carried out: degradation (e.g., hydrolysis, biodegradability; photodegradation in water,on plants,or on soil);metabolism (aerobic or anaerobic, in soil or water); mobility (leaching, adsorption in soil, desorption, remanence in ground or underground water); and accumulation (e.g., in members of ecological chains such as insects, fish, birds, and mammals).

Radioisotopes for Studying Pesticide Residue Problems. Radioisotope-labeled pesticides are used for studying the distribution, metabolism, and excretion of pesticides administered todomestic animals. Thus, ^{32}P-labeled organophosphorus pesticides used against internal and external cattle parasites (grubs inside the bodies of cattle, lice, ticks, horn flies, and other pests) served to trace the distribution of the pesticides and their metabolism in meat and milk and the excretion via urine and feces [144].

The metabolism and retention of chlorinated insecticides such as aldrin, dieldrin, and related products were studied by means of ^{14}C- and ^{36}Cl-labeled compounds, and contributed to evidencing the accumulation in fatty tissues of such compounds; the legislation restricting the use of such chlorinated products was a direct result of such studies, after similar results had been obtained with DDT and γ-hexachlorocyclohexane.

Isotope dilution methods can be used advantageously for the assay of pesticides in the environment. Higher sensitivity is

attained by double isotope derivative assay methods.

Application of pesticides in larger amounts than actually needed results in unnecessary spending of resources and increased amounts of residues causing undesirable ecological effects. Knowledge of the behavior and biology of the pest in its ecological context, and of the effect of the pesticide, are essential for correct application. Radioisotopes play an indispensable role in the research for less persistent and more potent pesticides, as well as for their efficient application.

5.5. Uses in Recombinant DNA Research (see also ⟶ Genetic Engineering; ⟶ Nucleic Acids)

The revolution in modern biotechnology and in genetic engineering is mainly due to recombinant DNA techniques, which in turn would not have been possible without the high sensitivity of radioactive methods.

Radioactive compounds have been essential in recombinant DNA work owing to their high sensitivity of detection: single-copy human genes can be detected in as little as 5 µg total genomic DNA, i.e., the limit is 1 – 10 pg.

Most studies have been made with ^{32}Plabeled compounds for obtaining nucleic acid precoursors with high specific activity (most commonly α-^{32}P-labeled deoxynucleotide triphosphates dATP or dCTP) [145].

In some cases, it may be advantageous to use ^{35}S or ^{3}H for labeling nucleotide analogues, especially when longer half-life and radiations of lower energy are desirable. In some applications requiring the use of labeled proteins, ^{125}I-labeling is used.

There are two main methods for sequencing and mapping DNA macromolecules, both published in 1977, the *Maxam and Gilbert* and the *Sanger method* (⟶ Genetic Engineering).

Maxam and Gilbert's specific chemical cleavage starts with a DNA which is labeled at the phosphorus atom bound to the 5′-hydroxyl terminus in the presence of polynucleotide kinase. This labeled DNA is then randomly cleaved at one of the four nucleotides: *purines* are methylated by dimethyl sulfate (guanine at N-7, and adenine at N-3), then heating at neutral pH causes breakage of the chain at guanine, whereas heating in dilute acidic solution breaks the polynucleotide chain both at adenine and guanine; for *pyrimidine-specific* cleavage, treatment with hydrazine followed by cleavage with piperidine leads to cleavage at cytosine and thymine, while hydrazinolysis in the presence of 2 N NaCl leads to breakage at cytosine only. Each of these reactions is carried out separately and the four specifically cleaved reaction mixtures are then separated on four lanes by downward electrophoresis on a polyacrylamide gel which resolves DNA molecules differing in their lengths. The resulting fragments are separated on the basis of their size, the shortest chains have the highest electrophoretic mobility. Because the starting DNA fragment is radioactively labeled at the 5′ end the fragment on the gel can be detected by autoradiography. The sequence can be read directly from bottom to top, according to the G; A + G; C + T; and C lanes [146].

Sanger's Dideoxy Sequencing Method (controlled interruption of replication). In this method new radioactive DNA strands of different lengths are synthesized on the DNA template, all strands ending at one of the four different bases. Incubation involves five components: the DNA template (usually single-stranded, produced via bacteriophage m 13), a primer (short single-stranded polynucleotide obtained from a restriction enzyme or chemical synthesis), DNA polymerase (*E. coli* DNA Polymerase I — large fragment or Klenow fragment) ⟶ Enzymes – Klenow Enzyme, all four nucleoside triphosphates (one or several of which are radioactive, usually the deoxyadenosine triphosphate), and one each (for each lane) of the four chain terminators (usually 2′,3′-dideoxynucleotide triphosphates ddATP, ddGTP, ddCTP, ddTTP). The primer is annealed to the template which leads to the elongation of the primer with nonradioactive nucleotides (dGTP, dCTP, dTTP) and with the radioactive derivative of dATP which is usually [α-^{32}P]dATP [2′-deoxyadenosine-5′-[α-^{32}P]-triphosphate (**1**)] or [^{35}S]dATP αS [2′-deoxyadenosine-5′- α[^{35}S]thio-triphosphate (**2**)].

1

[α-^{32}P]dATP

2′-Deoxyadenosine-5′-[α-^{32}P]-triphosphate

2

[^{35}S]dATPαS

2′-Deoxyadenosine-5′-α[^{35}S]thio-triphosphate

When a chain terminator is incorporated into the chain no phosphodiester can be formed since the chain has no 3′-hydroxy group and chain growth stops. If the concentration of dideoxynucleotides is limiting, then chain terminations will occur at every nucleotide so that all possible chain lengths will be obtained. Electrophoresis on polyacrylamide sequencing gels leads to clean separation of fragments on the basis of increasing size on the four lanes corresponding to the four types of 3′-end bases. Detection of these fragments is easily accomplished by autoradiography, then the sequence can be read directly from the four lanes, starting from the bottom [147], [148].

Sanger's dideoxy sequencing method has been continuously improved and offers many advantages. Accordingly, it has been the preferred method for large sequencing projects and for automation [149]. The Maxam – Gilbert method needs two separate steps, DNA labeling is tedious and requires the presence of suitable restriction sites, and, moreover, a systematic primer walking strategy cannot be applied.

The typical shelf life of ^{32}P-labeled nucleotides is about one month, whereas ^{35}S-labeled nucleotide analogues have shelf lives of at least three months. In addition, the weaker β emission of ^{35}S allows sharper autoradiograms (important in sequencing large DNA fragments) and obviates the need for lead shielding. Moreover, DNA labeled with ^{35}S is more stable than DNA labeled with ^{32}P, probably because of the phosphorothioate linkage which is resistant to many phosphodiesterases and nucleases, and because there is less radiation damage by the weaker β radiation of ^{35}S [150], [151].

Hybridization Probes (⟶ Nucleic Acids – Hybridization Techniques for Nucleic Acid Detection). Radioactively-labeled nucleic acids can function as hybridization probes for obtaining information on specific nucleic acid sequences which are present in a large mixture of unrelated sequences. This means in practice the identification and characterization of specific genes and DNA fragments, and the monitorization of gene expression.

Although the formation of hybrids can be also monitored optically or by fractionation on columns, radioactive methods allow the use of very small amounts of materials, and autoradiography is particularly convenient for detecting hybrids immobilized on solid supports such as nitrocellulose.

A restriction DNA fragment containing a specific base sequence can be identified by hybridizing it with a labeled complementary DNA strand. After separating the restriction fragments by gel electrophoresis, denaturation to form single-stranded DNA, and transfer to a nitrocellulose sheet, a particular sequence can be identified by formation of a hybrid with a ^{32}P-labeled single-stranded DNA probe (⟶ Genetic Engineering – Nucleic Acid Hybridization).

5.6. Uses in Biochemistry (for uses in medicine see Chap. Production of Artificial Radionuclides)

A few landmarks on radioisotope uses in biochemistry since the 1950 are given in the following.

In 1952, A. HERSHEY and M. CHASE [152] labeled T 2 bacteriophage DNA with ^{32}P, and its protein coat with ^{35}S. A sample of *Escherichia coli* infected with the labeled virus (T 2 phage) was separated by high-speed centrifugation leaving the virus in the supernatant and agglomerated the infected bacteria. It was found that most of the phage DNA appeared in the

infected bacteria while most of the phage protein appeared in the supernatant. The infected bacteria conserved their capacity to produce progeny virus; little parental ^{35}S but 30 % of parental ^{32}P was transferred to the progeny. In conclusion, the DNA and not the protein is the genetic information carrying part, confirming what AVERY, MACLEOD, and MCCARTY had inferred eight years earlier.

In 1958, A. KORNBERG used ^{14}C-labeled deoxythymidine in his discovery of DNA polymerase I which catalyzes step-by-step addition of deoxyribonucleotide units to the 3′-end of a primer chain with a free 3′-hydroxy group. These units are complementary to a template DNA molecule [153].

In 1961, BRENNER, JACOB, and MESELSON used both stable (^{15}N, ^{13}C) and radioactive isotopes (^{14}C, ^{32}P, ^{35}S) to prove that ribosomes synthesize at a given time the specific protein that is dictated by the messenger RNA (mRNA) they happen to contain.

Also in 1961, S. SPIEGELMAN used ^{32}P-labeled T 2 phage mRNA and ^{3}H-labeled T 2 DNA for showing that RNA –DNA hybrids are formed when they have complementary sequences [154].

The deciphering of the genetic code by M. NIRENBERG [155] and by H. G. KOHORANA [156] in 1962 – 1966 involved radioactive ^{14}C-labeled amino acids incorporated into proteins by a cell-free protein synthesizing system containing synthetic polynucleotides with known sequences. Such mRNA is synthesized by polynucleotide phosphorylase from given nucleotides.

Radioautography of the DNA of *Drosophila melanogaster* confirmed the existence of very large DNA molecules. A *D. melanogaster* chromosome contains a linear unbranched chain with a molecular mass of 43×10^{9}, i.e., 76 megabase pairs. The incorporation of radioactive labels into the chromosome was carried out over several generations by feeding these fruit flies with radioactive precursors [157].

Protein chemistry, nucleic acid chemistry, immunology, and molecular genetics are highly synergistic; powerful and highly sensitive radioactive methods allow minute amounts of genetic material to be amplified by gene cloning. A gene or cDNA (complementary DNA) can be inserted into an expression vector for infecting a host cell, e.g., an *E. coli* bacterium, and for producing the encoded protein. Alternatively, given a protein, its amino acid sequence can be determined, DNA probes synthesized for hybridization, and a DNA library can be screened by Southern blotting for isolating and cloning the respective gene or cDNA (⟶ Genetic Engineering).

Correspondingly, immunochemical methods can be used, starting with the gene or cDNA via the deduced amino acid sequence and the preparation of synthetic peptides for obtaining an antibody specific for the encoded protein; alternatively, starting from a given protein, a specific antibody can be prepared, and then via Western blotting a DNA library for arriving at the gene or cDNA can be contrived.

Fetal DNA *in utero*, or chromosomal DNA in any human, can be analyzed by restriction enzyme digestion followed by Southern blotting with a ^{32}P-labeled probe for the presence of genetic diseases such as sickle cell anemia, thalassemia, hemophilia, etc.

6. Syntheses of Radiolabeled Compounds

Walter Wolf

6.1. Introduction

Radiolabeling is the process whereby a radioactive nuclide is introduced into a chemical compound. Consider a very simple molecule, such as hydrogen (H_2). If every single atom of each hydrogen molecule were tritium (^{3}H) this would be a preparation that is *carrier-free.* While this is theoretically possible, the more likely situation is that a sample of radioactive hydrogen contains a mixture of ^{1}H and ^{3}H. The nonradioactive isotopes are called the *carrier* atoms, and it can be estimated from the *specific activity* of the material how much of each nuclide is present. Specific activities are expressed in activity per unit mass. Thus, carrier-free tritium would have a specific activity of 29.1 Ci/mol (i.e., 3 g), and the mass of tritium gas required to provide 1 Ci of material would be 0.103 mg. Thus, if a sample of tritium has a specific activity of 1 Ci/mg, this means that only 10 % of the hydrogen atoms present are tritium, and 90 % of the hydrogen atoms are ^{1}H (containing, presumably a small proportion of ^{2}H). In practice a much smaller proportion of radioactive atoms is used to radiolabel materials, inasmuch as the radiolabel is usually required only as a tracer — i.e., as a means of detecting the molecular species that contain that atom. The value of the activity – mass relationship can be calculated using the radioactive decay law. The mass (in grams) of a radionuclide that corresponds to 1 mCi is given by:

$$\text{mass (of 1 mCi)} = A_r \cdot t_{1/2} \cdot 8.87 \times 10^{-17}$$

where the half-life ($t_{1/2}$) is expressed in seconds. Radiolabeling with truly carrier-free radionuclides is rarely required, and radionuclides of medium to high specific activities are generally satisfactory. Table 7 lists selected activity – mass relationships of some of the more common elements used in the radiolabeling of organic compounds: This table includes two extremes: ^{14}C, with a $t_{1/2}$ of 5568 a, is probably the longest-lived radionuclide used for radiolabeling purposes, while ^{15}O — whose $t_{1/2}$ is only 2 min (123 s) — is probably one of the shortest of those that can be used for radiolabeling.

Table 7. Selected activity – mass relationships of the most common radionuclides used in the radiolabeling of

organic and biological molecules [a]

Nuclide	$t_{1/2}$	Mass of 1 mCi, mg	Maximum specific activity, mCi/mmol
^{3}H	12.262 a	1.03×10^{-4}	2.91×10^{4}
^{11}C	20.34 min	1.19×10^{-9}	9.24×10^{9}
^{14}C	5568 a	0.224	64.2
^{13}N	9.95 min	6.89×10^{-10}	1.89×10^{10}
^{15}O	123 s	1.64×10^{-10}	9.15×10^{10}
^{18}F	109.7 min	1.05×10^{-8}	1.71×10^{9}
^{32}P	14.22 d	3.49×10^{-6}	9.17×10^{6}
^{35}S	87.2 d	2.33×10^{-5}	1.5×10^{6}
^{123}I	13.3 h	5.22×10^{-7}	2.26×10^{8}
^{125}I	60.2 d	5.77×10^{-5}	2.17×10^{6}
^{131}I	8.05 d	8.08×10^{-6}	1.62×10^{7}

[a] From [158].

Radiolabeling may be performed by substitution or replacement of one of the atoms of a molecule with one of its radioisotopes (*intrinsic labeling*). In other cases, such as in the use of iodine for radiolabeling proteins, the iodine atom is not originally present in the parent molecule, but is added (*extrinsic label*). While intrinsic radiolabeling does not change the chemical nature of the original molecule, extrinsic radiolabeling may do so and it must be checked whether it does or not. The method of radiolabeling may become very critical in determining such chemical changes.

Another problem is where in the molecule the radiolabel will be placed. As an example, consider uracil, one of the key pyrimidines. The ring contains four carbon atoms of which carbon-2 is the easiest to radiolabel, as the 1 – 3 chain is formed from urea during biosynthesis. However, when uracil is catabolized, the first atom that is split off is C-2. To monitor catabolites such as fluoro- β-alanine, it is necessary to radiolabel the carbons at positions 4, 5, or 6.

Thus, more than one *radioisomer* exists in this case, and it is important to select the method of radiolabeling that will yield the desired compound with the radionuclide(s) at the desired position. Radiolabeling may be *specific*, i.e., the position of the radionuclide in the molecule is known. It may be *uniform* (U) or *general* (G), which means that a radiolabel is present at all the nonexchangeable positions in the molecule, or it may be *nominal* (n), which means that the location of the radionuclide has not yet been determined. It is very important to follow a uniform system of nomenclature, and to acquire as much information as possible on the position of the radiolabel. The purity of the final product must also be known: *radionuclidic purity* is a measure of the proportion of the desired radionuclide in the total radioactivity present, whereas *radiochemical purity* refers to the chemical identity and purity of the radiolabeled product.

The *stability* of the radiolabeled material is one further consideration that is very critical. Energy is continuously being released within the radiolabeled material, leading to the production of radiolysis products in addition to the decomposition products derived from those molecules in which an atom has decayed. Thus, although tritium has a $t_{1/2}$ of 12.262 a, the shelf life of tritiated compounds is usually measured in weeks (or a few months, at most). It is critical that the user of radiolabeled materials documents the radiochemical purity of the material at the time of use and performs additional purifications if needed.

Many of the labeling techniques (albeit, not the accompanying precautions) described in the following have also been used for the preparation of compounds labeled with stable isotopes of key elements, such as deuterium, ^{13}C, and ^{15}N.

A number of treatises discuss radiolabeling in much greater detail, in books [159-163], in symposia [164-169], in review articles and book chapters [170-174], as well as in a very large number of original papers.

Chemical differences can be observed between compounds labeled with isotopes (see also ⟶ Isotopes, Natural – Chemical Differences). This occurs in all reactions where the mass of the material is key to the rate determining step. Such phenomena are known as *isotope effects* [175]. They are of special importance for hydrogen, whose isotopes have twice (^{2}H) or three times (^{3}H) the mass of the regular hydrogen (^{1}H). Such differences still exist for carbon, where the ^{14}C/

^{12}C mass ratio is 1.16667, and the $^{12}C/^{11}C$ mass ratio is 1.091. It is reduced to 1.03 for iodine ($^{127}I/^{123}I$). Isotope effects need, on a practical basis, be considered important only in reactions involving deuterium and tritium.

6.2. Principles of Radiolabeling

6.2.1. *Introduction*

A number of companies prepare radiolabeled compounds on a routine basis, and investigators should consult their appropriate catalogues to determine what may be available. Most of these companies are also willing to undertake custom syntheses. Whether a radiolabeled compound is prepared "in house" or commercially, certain general principles always apply:

1. The radionuclide of choice must be selected, as well as the position(s) on the molecule to be radiolabeled.
2. The investigator must be aware of how this radiolabled compound will be used, in order to estimate what specific activity is required, how much total activity will be needed, and which atom(s) of the molecule should be radiolabeled.
3. The investigator must also be familiar with all the appropriate safety aspects for handling of the radionuclide. Thus, very different shielding will be required for ^{3}H, a very soft β emitter (E_{av} = 6 keV), than for a positron emitter (511 keV annihilation radiation). In all cases, in particular with biological tritium compounds, absolute care must be taken to avoid ingestion, inhalation, or other internalization of the radiolabeled material.
4. The required equipment for correct (remote and enclosed) handling of radioactive materials must be available, and each investigator must become familiar with such techniques.

6.2.2. *Methods of Radiolabeling*

Methods used for radiolabeling can be divided into chemical and biological methods. *Chemical methods* include: (1) Direct chemical synthesis; (2) exchange labeling, where an existing cold (nonradioactive) atom is replaced by its hot (radioactive) isotope; and (3) recoil labeling, where the primary radioactive atoms that are chemically excited can be used directly. *Biological methods* include both those performed in vivo and in vitro.

The actual synthesis is only the first step. The isolation and purification of the radiolabeled product is sometimes as difficult and time consuming as the original preparation, if not more so. This is because of the amounts of product involved (often in the milligram or microgram range) and of the precautions that need to be taken during the preparation. HPLC, either preparative or analytical, is one of the most widely used purification techniques.

A key consideration in any synthesis of a radiolabeled compound is that the radionuclide should be introduced at the latest stage possible. This is because any "hot" synthesis requires special handling, it must be accomplished within a limited period of time, and low yields obtained may become extremely costly. Time is of particular importance when using some of the very short-lived radionuclides where syntheses must be completed within less than 2 – 4 half-lifes of the radionuclide. For these reasons the synthetic methods used in radiolabeling may differ from those employed on a larger scale and where time is not a primary consideration. As an example, it was required to radiolabel 5-fluoro-uracil (5FU), a key antitumor agent, with ^{18}F. The standard method of synthesis of (cold) 5FU starts with a fluorinated intermediate, and takes place over two days. Such a method is obviously totally impractical for the introduction of the short-lived (109.7 min) ^{18}F into 5FU. The alternative synthesis that was developed allowed the preparation of a clinical dose of ^{18}F-5FU in a 45 % radiochemical yield in 45 min from EOB, including its purification and sterilization for human use [176].

While most conventional syntheses (organic or inorganic) can be adapted to the preparation of radiolabeled compounds the scale of the synthesis may have a significant effect. Syntheses that lead to good yields with gram amounts of starting materials may not scale down well to milligram or microgram levels. Such scaling phenomena are not always well understood, but some of the more common problems are due to changes in heat transfer rates, levels of interfering contaminants, changes in solvents, etc.

Direct syntheses include all those methods of radiolabeling based on standard and well established synthetic methods from organic and inorganic chemistry, where the previously noted constraints of time, scaling, yield, and safe handling must be taken into account. All that is needed is adaptation of a new synthetic pathway to provide the amounts of material available for a radiosynthesis.

Exchange reactions of the type

$$AX^* + BX \rightleftharpoons BX^* + AX$$

allow for the replacement of a given atom by a corresponding radioactive isotope. This technique is most widely used for atoms that form only one single bond, such as the halogens or hydrogen. Yields in such reactions are usually low, but because they only require one step (followed by purification), their time normalized yields may still be acceptable.

Recoil reactions take advantage of the fact that radionuclides, upon production, still have excess (recoil) energy, and that they will react with almost anything present in their environment. If that environment is properly controlled, the radiolabeled intermediates can effectively be used later in a synthesis. Thus, in the production of ^{18}F by the $^{20}Ne(d, {}^{4}He)$ reaction, 0.1 – 1 % cold F_2 is added to the neon gas so that fluorine atoms in F_2 will exchange with the (kinetically) hot $^{18}F^{**}$ produced in the nuclear reaction.

Biological methods make use of whole living systems, tissues removed from such living systems, or isolated enzymes. They are capable of producing and/or transforming very complex molecules quite rapidly, and they permit radionuclides to be introduced at specific positions in a very selective manner. However, these methods are limited to molecules that can

be transformed by enzymatic reactions, and although they are highly selective, yields are usually low.

6.2.3. *Stability of Radiolabeled Compounds*

Another factor to be considered is the stability of the radiolabeled material. Such materials contain, by definition, atoms that decompose, giving rise to both reactive and stable decomposition products. A much larger quantity of reactive products is formed as a consequence of the interaction of radiation with matter: hydroxyl free radicals (OH), hydrogen free radicals (H), and the hydrated electron (e^-_{aq}) result from the interaction of α, β, or γ radiation with water, and free radicals arise from the interaction of radiation with other molecules. While the chemical entities resulting from subsequent reactions with these reactive intermediates may or may not be radiolabeled, they will contribute significantly to an ever-increasing deterioration of the purity of the radialabeled material.

Phosphorus-32, for example, has a $t_{1/2}$ of 14.22 d, which means that the inherent rate of decomposition of a ^{32}P-labeled material is 4.83 %/d. In a product that is seven days old, 32.7 % of the ^{32}P-phosphorylated material will have decomposed. Such impurities become more significant the higher the specific activity. While ^{32}P has a maximum specific activity of 9.17×10^6 Ci/mol, the specific activity of most ^{32}P-labeled materials is in the range 10 –100 mCi/g, which means that only 0.03 % of all phosphorus atoms are radiolabeled, hence only 0.01 % of the total phosphorylated product will have decomposed in one week. However, to this impurity level,the products of the radiolytic reactions must be added. The more chemically sensitive the molecule, or the higher its specific activity, the higher the probability of decomposition. It is therefore important that any laboratory intending to use radiolabeled materials has a system of quality control in place in order to ascertain the purity of the radiolabeled products. A number of methods have been developed for the preservation and purification of radiolabeled compounds [170], [177].

The discussion that follows on specific types of radiolabeling is divided into four sections:

1. ^{14}C, ^{3}H, ^{32}P, and ^{35}S, all pure β emitters
2. Short-lived positron emitters (^{11}C, ^{13}N, and ^{15}O)
3. The halogens, including ^{18}F and the various radio-iodines
4. Radiometals and radiolabeling with other elements

6.3. Radiolabeling with ^{14}C, ^{3}H, ^{32}P, and ^{35}S

^{14}C. A general scheme for the preparation of ^{14}C-labeled materials is presented in Figure 35. The central starting material is $^{14}CO_2$, usually prepared by the addition of sulfuric acid to $Ba^{14}CO_3$. A simple manifold system can be used to handle such radioactive gases and ensure that transfers and reactions occur in a closed environment.

Figure 35. Scheme for the preparation of ^{14}C-labeled materials from $^{14}CO_2$

The yield for each reaction and the reagents reacting with $^{14}CO_2$ are listed above for each of the key intermediates formed. Each of these primary intermediates can then, in turn, be used in a variety of synthetic steps. Some aspects of these reactions are illustrated with the formation of ^{14}C-acetic acid. Actually, there are three radioisomers of ^{14}C-acetic acid: 1-^{14}C-acetic acid, 2-^{14}C-acetic acid, and 1,2-^{14}C-acetic acid, and the following set of reactions illustrates how each these three different compounds can be synthesized.

If the purpose of the study is to use ^{14}C-labeled acetic acid to determine the degree of incorporation of its methyl group into an organic or a biological molecule, then either 2-^{14}C-acetic acid or the 1,2-^{14}C-derivative must be used. The first of these is preferred: all its activity is in the methyl group, and any activity detected must come from that function. The doubly labeled acetic acid would be a poorer choice, inasmuch as up to 50 % of the activity in the final product would either be lost or come from some source other than the methyl group. This example illustrates why it is important to understand the purpose of a study before selecting the radiolabel to be used and the method of radiolabeling.

As noted previously, the ultimate starting material for all ^{14}C syntheses is $^{14}CO_2$. Radioactive carbon dioxide can easily be frozen, transferred, and reacted in closed and remotely-controlled manifolds. Because of the long half-life of ^{14}C, radiolabeled compounds containing this radionuclide are widely available and many suppliers are also willing to perform custom syntheses.

Selected carbon-labeled compounds can be and have been prepared by biochemical methods. For example, incubation of ^{14}C-acetic acid with liver tissue leads to ^{14}C-cholesterol as well as its precursors and metabolites, all of which can then be isolated and purified. Radiolabeled alkaloids and other natural products can also be prepared biochemically, and biotechnology is beginning to be used to generate specific novel ^{14}C-radiolabeled materials whose direct synthesis has not yet been achieved.

^{3}H. Tritium is probably the most widely used radionuclide in biochemical studies. Its half-life of 12.262 a makes compounds radiolabeled with this radionuclide readily available from commercial sources and it can be obtained in much higher specific activities than are available with carbon (up to 29 Ci/mol). Chemically, the single bond, between hydrogen and carbon (in organic molecules) makes it relatively easy to achieve radiolabeling, and the very low energy of the β radiation (18 keV E_{max}) makes it very simple to provide shielding from tritiated materials as external emitters. On the other hand, tritiated thymidine — probably one of the most widely used tritiated compounds since it can monitor DNA synthesis — is also one of the most radiotoxic substances when it is internalized, because all its energy is deposited in the DNA of cells at the site of incorporation — which, in humans, would be the gonadal and the hematopoeitic tissues.

Exchange labeling is very widely used for tritiation. Palladium, platinum, and other catalysts can activate tritium (usually furnished as tritiated water) with hydrogen replacement in organic molecules upon heating. Radiolabeling by this method is usually general, but rarely uniform. Radiation-catalyzed exchange reactions (e.g., Wilzbach technique) are also very effective and give high yields, but they have the drawback of requiring very extensive purifications.

Specific tritiations can best be achieved by using chemical reduction methods; e.g., reduction of a halogen compound in the presence of zinc and tritiated water; hydrolysis of a Grignard reagent (ArMgX) by T_2O; reduction of a carbonyl compound with tritiated sodium borohydride or reduction of a halogen compound with tritium gas in the presence of a palladium or platinum catalyst. One caveat: the exact position and specific activity of the final product must be documented, inasmuch as hydrogen migrations may occur during the radiolabeling process.

^{32}P and ^{35}S. Both of these radionuclides are relatively short-lived ($t_{1/2}$ 14.22 d and 87.2 d, respectively), and very few compounds labeled with these radionuclides are commercially available. However, most *radiolabeling with ^{32}P* — obtained either by the activation of ^{31}P or in much higher specific activity by the (n,p) reaction of ^{32}S — is quite simple, inasmuch as most of the compounds studied carry the radiolabel in a phosphate function. Labeling of the terminal phosphate of ATP permits transfer of the radiolabeled function to other phosphates. Other organophosphorus compounds of interest include insecticides, fertilizers, and industrial chemicals.

^{35}S is obtained either by the activation of ^{34}S (low specific activity), or by the (n,p) reaction of ^{35}Cl (high specific activity). Compounds containing either S(–II) (mercaptans) or S(+VI) (sulfates) have been prepared to study drugs and biochemical agents, fungicides, and insecticides. Industrially important sulfur-containing compounds that can be radiolabeled include surface-active agents and rubber additives.

^{11}C, ^{13}N, and ^{15}O. These three radionuclides (together with ^{18}F, see below) have found wide application as nuclides for PET studies. Their half-lifes (20.34 min, 9.95 min, and 123 s, respectively) make syntheses with these radionuclides a very unique and distinct specialty within radiochemistry and radiopharmacy. In practice a synthesis itself may occupy up to 6 half-lifes. Thus, starting with 1 Ci of a ^{11}C-containing reagent, 15 mCi of the original activity will remain after 6 half-lifes (120 min). The main problem is thus to select a synthesis that is fast, even though the absolute yield may be less than in a traditional preparation.

The chemistry used for the preparation of *^{11}C-labeled compounds* is the same as for the preparation of ^{14}C-labeled compounds, except that the time factor must be considered as a key element in the process. In addition, very significant shielding (hence, remote handling) is required. Typical syntheses with ^{11}C use 100 mCi or more of starting material, and most biological and human studies require 1 – 20 mCi per study. Another feature of such a synthesis is that a given preparation is usually limited to a single use, rather than for multiple uses and users as in most other syntheses with radionuclides. A high degree of coordination is also required: the experiment or study in which the ^{11}C compound will be used must be ready to start at the moment the synthesis is completed.

Yet another distinguishing feature is that the method used for preparing the radionuclide must be tailored to the subsequent chemical reaction. Thus, rather than making $^{11}CO_2$ and then generating from it a series of intermediates, as described above for $^{14}CO_2$, the usual procedure is to make the desired intermediate directly in the cyclotron. As an example, irradiation of ^{11}B [a (p,n)reaction] in the presence of NH_3 and K leads directly to $^{11}CN^-$, as does the irradiation of $N_2 – H_2$ mixtures using the ^{14}N (p, α) reaction.

Many compounds radiolabeled with ^{11}C have been prepared, and several are being prepared on a daily basis. These PET radionuclides constitute a unique tool for studying biochemical, physiological, and pathological changes inside living systems using what is fundamentally a noninvasive technique. They have already revealed unique features of processes inside the brain, which segments are activated when we hear, see, or receive other stimuli, and how such physiological

features change with age, disease, and drug treatment.

Syntheses with ^{13}N and ^{15}O are based on the same rules, with the caveat that the time available is much shorter. Thus, the only practical compounds that can be produced with a ^{15}O label are O_2, H_2O, and CO_2, together with their in vivo reaction products (e.g., with hemoglobin).

^{18}F, ^{123}I, and Other Halogens. All halogens have radionuclides that have been used for radiolabeling. Here the discussion is limited to the most widely used cases: ^{18}F and the radioiodines.

Fluorine-18. ^{18}F has a half-life of 109.7 min, and is therefore by far the longest-lived of the PET radionuclides. Taking the six-half-life rule as a guide, studies can be performed with compounds radiolabeled with ^{18}F for more than 600 min (10 h). The time window is thus significantly wider than with any of the other PET radionuclides. ^{18}F-2-fluoro-2-deoxyglucose (^{18}F-FDG) is the most widely used PET radiopharmaceutical, since it makes it possible to measure the metabolic status of various tissues and organs in which that molecule is metabolically trapped [173].

Radiolabeling with ^{18}F is not easy, given the nature of fluorination reactions. As with all halogens, fluorination can be envisioned using either an electrophilic fluorine or a nucleophilic fluoride ion (F^-). Inasmuch as fluorine is the most electronegative element, the possibility of removing an electron to yield a reactive F^+ species has been seriously questioned. In addition, fluorine in aqueous solution is extensively and strongly solvated, and such species must first be transformed into “naked” fluorine before they can be used in electrophilic substitution reactions. Removal of the water is difficult. Hence, even though nucleophilic fluoride is best be made by the (p,n) reaction of ^{18}O in $H_2^{18}O$, production of electrophilic fluorine must be accomplished under strictly anhydrous conditions using reactions such as the (d, α) reaction of ^{20}Ne [166], [173].

Dozens of reactions have been developed for making radiofluorinated species. As an example, ^{18}F-5-fluorouracil has been synthesized by the reaction of ^{18}F-F_2 [produced in the ^{20}Ne (d, α) raction] with uracil, fractional sublimation of the addition product, and purification of the final material. Yields of 45 % have been achieved in 45 min following end-of-synthesis [176]. ^{18}F-FDG is now prepared routinely in many laboratories throughout the world for PET studies; other ^{18}F-labeled compounds are being synthesized and used for measuring receptors, monitoring drug targeting, and, in general, to elucidate the mechanisms involved in the use of fluorinated agents.

Radioiodine was the first radionuclide used for human studies (in 1937), and it acquired a high profile when ^{131}I became readily available from reactors in 1945. Indeed, the first 20 years of application of radionuclides in humans were dominated by ^{131}I, and one of its isotopes, ^{125}I, remains the dominant radionuclide, used in nearly 90 % of all in vitro clinical radionuclide applications. Table 7 lists some of the key radioisotopes of iodine used in the mid 1980s. All share a common and very simple chemistry: iodination of proteins by electrophilic iodine (I^+, iodonium), readily produced by oxidation of iodide ion ($I^- - 2e^- \longrightarrow I^+$). Such an oxidation can be achieved with hydrogen peroxide, chloramine T, or enzymatically using lactoperoxidase. In proteins, iodination occurs at the 3 or 5 position of tyrosine. These positions have increased electron density due to the hydroxyl group on carbon 4, and facilitates electrophilic substitution. Typically, a protein is placed in solution, radioiodine is added (as iodide), and an oxidizing agent is introduced to start the reaction. The final product is then isolated and purified.

Nucleophilic displacement reactions (mostly exchange reactions) are employed when an iodine atom is required at a nonactivated position, such as in hippuran (2-iodohippuric acid). Addition of radioiodide and heating at 170 °C for 30 min readily exchanges the stable ^{127}I for one of its radioactive isotopes (^{123}I, ^{125}I, ^{131}I).

As mentioned above, ^{125}I is used primarily in laboratory studies. Its relatively long half-life (60.2 d) and low photon energies make it very suitable for such purposes. It is readily obtained in nuclear reactors by neutron activation of ^{124}Xe or ^{125}Xe, which then decays to ^{125}I. ^{125}I is not useful for imaging. ^{131}I is obtained mainly from the fission products of ^{235}U, and it is therefore available both in large quantities and at reduced costs. While its high photon energies (364 keV) and short half-life (8.05 d) make it no longer the best radionuclide for human imaging studies (a position now held by ^{99m}Tc), it is still a very valuable and widely used species. ^{123}I on the other hand, is ideally suited for imaging studies: it has a half-life of 13.3 h, and a photonenergy of 159 keV. However, it is much more difficult to make than ^{99m}Tc and hence much more expensive. It is used for special studies in which its chemistry offers unique advantages.

^{59}Fe, ^{111}In, ^{99m}Tc, and Other Radionuclides. Labeling has also been achieved with other elements. Modern nuclear medicine, which is primarily based on the use of products radiolabeled with ^{99m}Tc, has required the development of novel, specialized reactions for dealing with this man-made element, known only since 1937 (see Section Technetium). The reader is referred to specialized literature for further information.

7. The Biological Effects of Radiation and Radionuclides

Albrecht M. Kellerer and Jürgen Griebel

The assessment of the health hazards arising from ionizing radiation has undergone a striking change in the course of this century. When RÖNTGEN announced in 1895 that he had discovered a new type of radiation, which he called X-rays, the world reacted with an immense faith in progress. Although harmful side effects of X-rays were soon encountered, no one

thought about hazards or radiation protection. Inflammation similar to that caused by burns was observed on the hands of operators repeatedly testing X-ray pictures and, later, the first cases of radiation-induced skin cancer became known. Only a decade after the discovery of X-rays, an increased frequency of leukemia among radiologists was noticed [178]. This was not regarded as a warning sign but, at best, as an indication of the possible hazards arising from the long-term exposure to high doses of radiation.

The positive expectations that were aroused by this new agent are reflected in the application of X-rays and natural radioactivity (which was discovered just a year later) in medicine within few weeks after the discovery by RÖNTGEN. X-rays were being used extensively in the examination of the human body and first in simple medical diagnoses. Radioactivity was also quickly applied for all kinds of medical therapy and especially radium, with its penetrating γ radiation, was frequently and indiscriminately used at the start of this century in a large number of diseases and for the supposed stimulation of the organism. For instance, the application in the form of radium pillows was common, even in the absence of disease and without medical supervision.

Early fundamental work in radiation biology, e.g., by the young FRIEDRICH DESSAUER [179], showed that higher doses of ionizing radiation destroy living cells. This finding quickly led to the introduction and subsequent improvement of radiation therapy for cancer patients. In spite of the accumulated results on the biological effects of ionizing radiation, the belief in the harmlessness of low doses of radiation persisted for decades.

The fate of hundreds of young women, especially in the United States, who painted the faces of clocks and instruments with luminous paint containing the long-lived, α-emitting ^{226}Ra was one of the first great tragedies resulting from unprotected exposure to radionuclides. Since they had not been warned of possible hazards, the workers sharpened their brushes soaked in luminous paint with their mouths, thus incorporating considerable amounts of activity. Many of them died of bone tumors [180], [181]. A young doctor published his suspicions, that the severe lesions in the jaws of the young women could be caused by radiation. In response, he was called a charlatan by a reader because, as was explained in the reader's letter, it was common knowledge that radiation was dangerous only in massive overdoses over long periods of time. The letter was written by the great scientist Marie Curie, who herself fell victim to radiation exposures later.

These and similar examples illustrate the consequences of the uncritical contact with ionizing radiation which took place in the first half of this century. A fundamental change in assessment of radiation hazards occurred, when the long-term effects of radiation exposure were discovered in the survivors of the atomic bombings of Hiroshima and Nagasaki. The possibility that leukemia might result from a single and relatively small dose of radiation was proposed by LEWIS in the 1950s [182]. He inferred from the increased frequency of leukemia among the survivors of the atomic bombings — about a dozen cases per year — that leukemia could result from somatic mutations, i.e., individual alteration in the DNA of single cells. This finding became the basis for the present philosophy of radiation protection, which holds the principle that unnecessary exposure to radiation should be prevented and unavoidable exposures should be reduced as far as possible.

The recognition that even the smallest doses of radiation can — with correspondingly low probability — cause hereditary defects or cancers and the fact that this possibility was recognized first for radiations, and only later for chemical carcinogens, may have led to the amazing change in the attitude to ionizing radiation. In the past, people had blind faith in the mysterious biopositive effects of radiation, but now the risks, which must indeed be taken seriously, are often overestimated in comparison with other risk factors.

7.1. Physical Radiation Effects (see also ⟶ Nuclear Technology – Radiation Protection and Safety)

Several levels can be distinguished in the effects of ionizing radiation: physical, molecular, cellular, and tissue effects (Fig. 36).

Figure 36. The different levels in the action of ionizing radiation

In spite of considerable differences in the energy transport and interactions with matter (see Chaps. Introduction and Detection of Ionizing Radiation and Radionuclides), all types of ionizing radiation act through the same physical primary processes and, as discussed later, they all act predominantly by damaging the DNA, i.e., the genetic material of the cell. *Indirectly ionizing radiation*, i.e., photons and neutrons, release fast particles in matter. The charged particles are, in turn, ionizing and produce secondary electrons which cause the major part of the ionizations and excitations. In the case of excitation, the excited molecule dissociates into radical or nonradical products or it gives up its energy to the environment without disintegrating. In comparison with ionizations, however, electron excitations are of secondary importance for radiation effects. In the case of *directly ionizing radiation*, such as electrons or α particles, charged particles are present from the start.

The photons of X-rays or γ-rays generated in nuclear decay and energy-rich neutrons have substantial penetrating power in tissue. The high-energy electrons produced in an accelerator can also penetrate deeply into tissue. In contrast the electrons of β radiation, which are produced in radioactive decay, have a range of only a few millimeters in tissue. For this reason, β emitters are active primarily when they are incorporated. The same applies to α emitters. As a result of their short range, they are of importance only in the case of inhalation or ingestion of radionuclides.

Since the primary physical and chemical effects are identical for all types of ionizing radiation, the same quantity can be used to measure the extent of a radiation exposure. This quantity is called the *absorbed dose, D*, or simply the dose (see Chap. Introduction). The unit used, to express the absorbed dose, is J/kg, or gray (Gy). In spite of the identity of the physical primary processes, the various types of radiation have, even at the same absorbed dose, different efficiency in the cell or tissue. The reason for the differences lies in the varying microscopic concentration of the energy transferred along the tracks of the various particles (Fig. 37). *Sparsely ionizing radiations*, such as γ-rays, X-rays, or fast electrons, cause only a few dozen ionizations along their path through the cell. The resulting direct and indirect damage to DNA (see Section Molecular Radiation Effects) can be largely repaired. *Densely ionizing particles*, such as the relatively slow, heavy α particles or recoil nuclei triggered by neutrons, cause thousands of ionizations as they pass through the cell. The clustered DNA damage produced within a small site can often be only imperfectly repaired (see Section Molecular Radiation Effects). The difference between the various types of radiation is quantified by the linear energy transfer (LET), i.e., the rate of energy loss per unit distance.

Figure 37. Schematic representation of the tracks of charged particles (from B. Alberts: Molecular Biology of the Cell, 1988)

To bring the frequency and spatial distribution of the ionizations into relationship with submicroscopic cell structures, a part of an electron micrograph of a cell is used as the background. Virus particles can be seen budding outward from the cell membrane. The electron tracks that are shown can also be regarded as typical of the fast or slow electrons triggered by X-rays or γ-rays. The proton tracks also represent the case of neutron irradiation, because neutrons produce predominantly fast protons in the tissue.

In the application of ionizing radiation in *tumor therapy*, the different efficiency of the various types of radiation must be carefully evaluated. Moreover, the effect ratio depends in a complicated manner on the dose and the dose distribution in time. Simplified evaluations of radiation quality are adequate for the purpose of *radiation protection*, where low doses are involved and, furthermore, only summary estimates are required of effects that are possible, but less likely to occur.

Radiation protection summarily takes into account the different efficiency of densely and sparsely ionizing radiation through the *quality factor, Q.* This factor represents the relative biological effectiveness of the different types of radiation with regard to the production, through DNA damage, of stochastic, long-term effects, i.e., hereditary damage or carcinogenesis (see Section Radiation Effects on Tissue). The International Commission for Radiation Protection (ICRP) has defined the quality factor as a function of the LET [183] (Fig. 38). The *dose equivalent, H*, is the product of the absorbed dose, *D*, times the quality factor, *Q*:

$$H = D \cdot Q \tag{7.1}$$

Figure 38. Quality factor as a function of the linear energy transfer, LET [183]

The corresponding ranges of LET are shown for some types of radiation.

To differentiate between the absorbed dose and the dose equivalent, the latter is expressed in the unit sievert (Sv).

7.2. Molecular Radiation Effects

The conversion from the physical to the molecular radiation effects is predominantly due to radicals generated by the ionization of a molecule. These radicals can quickly react with each other or with stable compounds in their environment. Two mechanisms of action can be differentiated. In the *direct radiation effect*, ionization and, consequently, radical formation occur in a biomolecule itself. In the *indirect radiation effect*, the primary radicals formed during the radiolysis of water react with the biomolecules. This mechanism plays the principal role in biological systems with their high water content.

7.2.1. *Radiation Damage to DNA*

DNA and its structural elements, the bases, and the sugar phosphate skeleton, can be chemically changed by direct and indirect radiation effects. One possibility is the formation of a *single-strand break* in the DNA double helix, the complementary strand remaining intact. Another possibility are *double-strand breaks* resulting when both strands are damaged at closely neighboring positions and when, as a result, the DNA molecule is severed. Other alterations, that can occur, include changes in the chemical structure or sequence of the bases in the DNA strand.

There is a range of possible results of the molecular damage to DNA (Fig. 36):

1. Disturbances in replication and transcription
2. Gene mutations
3. Chromosomal aberrations

It is well established by numerous studies in radiation biology that DNA is the main target of the exposure to ionizing radiation. However, other structures may also be affected, the most important being biological membranes.

7.2.2. *Repair of DNA Damage in the Cell*

Damage to DNA can be caused by numerous noxious agents. Ionizing radiation represents only one, although important, example of these agents. Damage to DNA would very quickly lead to a loss of cell function in the absence of effective

repair mechanisms. In fact, the evolution of bacteria and higher cells would not have been possible without complex enzyme-controlled mechanisms for the repair of molecular damage to DNA. For instance, a defective base in a DNA strand can be excised and replaced by the insertion of nucleotides in the correct order, determined by the base sequence of the complementary strand. This repair involves the action of various enzymes.

As mentioned in Section Physical Radiation Effects , the different biological effectiveness of sparsely and densely ionizing radiation is closely related to the ability of the cell to repair DNA damage. The passage of individual sparsely ionizing electrons through the cell nucleus produces only few lesions in DNA, and these can be enzymatically repaired with high efficiency. In contrast, the passage of a single densely ionizing particle through the cell nucleus produces a large number of lesions in the DNA. These lesions are in close proximity and this leads, with high probability, to misrepair. At larger doses of several gray, the differences between both types of radiation play a less important role because a large number of DNA lesions will then also occur with sparsely ionizing radiation.

7.3. Cellular Radiation Effects

Ionizing radiation can cause a large number of changes in the chromosomes by damaging DNA. Depending on whether these cytogenetic changes are visible under the light microscope, they are divided into visible *chromosomal aberrations* (numerical or structural) and invisible *gene mutations* (Fig. 36). Even if gene mutations are not microscopically visible, their consequences can be serious. The division between chromosomal aberrations and gene mutations have become less distinct with the development of new molecular biology techniques (e.g., fluorescence in situ hybridization, see below).

Numerical chromosomal aberrations are deviations from the modal number of chromosomes (in humans 46 = 2×22 autosomal + 2 sex chromosomes). They give rise to aneuploid and polyploid cells. *Aneuploidy* is characterized by the lack or excess of individual or several autosomal or sex chromosomes, as in certain inborn diseases (trisomy 21, Turner or Klinefelter syn-drome). In *polyploidy*, the diploid number of chromosomes is increased by one or several sets of chromosomes. After exposure to ionizing radiation, the formation of cells with numerical chromosomal aberrations is a result of disturbances in the division of the cell nucleus (mitosis) or the cell (cytokinesis). Altered chromosomes, e.g., the dicentric chromosomes (see below), can disturb or prevent regular division of the cell or its nucleus. Radiation can also cause a disturbance of the spindle microtubules and thus interfere with mitosis.

Radiation-induced *structural chromosomal aberrations* are either simple fragment losses (deletions) which lead to the shortening of a chromosome, or structural rearrangements. The latter are produced when several breaks occur in neighboring chromosomes and the ends are joined to give abnormal configurations (Fig. 39). If, for instance, interactions occur between the chromosomes with one break each (interchromosomal exchange), symmetrical or asymmetrical structural rearrangements can occur. An *asymmetric chromosomal exchange* figure that arises from the joining of two fragments with one centromere each is the dicentric chromosome. If chromosome sections without a centromere are exchanged, *symmetric translocations* are produced. In the metaphase of mitosis, dicentric chromosomes are readily detected with conventional staining techniques under the light microscope. Symmetric translocations are more difficult to detect.

Figure 39. Schematic representation of the principal types of structural chromosome aberrations [184]

Both types of chromosome aberrations can be used as a biological dosimeter to estimate the radiation exposure of humans. The dose received can be determined on the basis of calibration curves by counting the frequency of radiationinduced chromosomal aberrations in the lymphocytes of blood. The dose estimation is usually performed through the determination of dicentric chromosomes, a significant increase being detectable only after a whole body exposure of about 100 mGy of X-rays or γ-rays. Since dicentric chromosomes interfere with the regular course of mitosis, the number of lymphocytes with dicentric chromosomes decreases with time after irradiation. For this reason, dose estimations for exposures that originated a long time ago are not very reliable. On the other hand, the number of cells with symmetric translocations remains largely unchanged for years, making this type of abnormality more suitable for the quantification of radiation exposure that is either chronic or that has taken place in the past. With the aid of *fluorescence in situ hybridization*, individual chromosomes can be specifically labeled over their entire length with chromosome-specific DNA probes. Thus, symmetric translocations with other chromosomes can be recognized. In the experimental procedure DNA samples are hybridized in situ with lymphocyte chromosomes, and labeled DNA sections are detected with a fluorescence-labeled antibody.

Radiation-induced chromosomal lesions can lead either to cell death or, in the case of less drastic damage, to nonlethal changes in the genetic material of the cell, which can culminate in malignant neoplasia (somatic cells) or hereditary disease (germ cells) (Fig. 36).

7.4. Radiation Effects on Tissue

In the past decades, a large amount of information on the effects of radiation doses has been gathered. High doses of radiation lead to severe, irreparable damage to DNA, resulting in cell destruction. If a dose of radiation exceeds a threshold that depends on the type of the tissue and the type of radiation, tissue damage results. The degree of damage, in turn, depends on the dose. No substantial effects are observed at doses below the threshold (*deterministic mechanism* of damage, Fig. 36) [183].

An important example of deterministic damage is the acute radiation sickness that occurs after a large exposure of the whole body. The $LD_{50/60}$, i.e., the dose of radiation that will kill a patient with a 50 % probability within 60 days after whole body exposure, is 3 – 5 Gy in the absence of special medical care [183]. Without treatment, death is possible after doses of 2 Gy. In the therapy for leukemia, whole body doses of 8 –12 Gy — protracted over several hours — are administered to condition the patient for a bone marrow transplantation. At these doses, the patient has no chance of survival without the bone marrow transplantation.

In contrast to deterministic effects — previously known as nonstochastic — *stochastic damage* refers to lesions in individual cells, and changes in their DNA that do not stop cell proliferation and that can lead to hereditary damage or to cancer (Fig. 36). In germ cells, changes of the DNA can cause inherited defects in the descendants of irradiated persons. Malignant diseases, which appear years or decades after exposure, can be induced in somatic cells. The development of a malignant (Section Radiation Carcinogenesis) or hereditary (Section Hereditary Radiation Effects) disease can result from the alteration of a single cell, although the probability of any single cell to cause this process is low. The dose does not determine the severity of the disease, but the number of affected cells and thus the probability of its occurrence. Stochastic effects have no threshold. Even small doses can — with correspondingly low probability — cause stochastic damage.

The absence of a threshold dose is not exclusively a characteristic of ionizing radiations. It is typical of all noxious agents with genotoxic effects. In the case of most chemical carcinogens, there is also no dose or concentration threshold below which harmful effects are impossible, and above which the risk increases. Therefore, the aim of protection against such substances, as well as ionizing radiation, can only be, to limit the risks to a level that can be neglected compared with existing hazards: exposures must be kept as low as reasonably achievable.

Prenatal exposure to radiation can cause developmental disturbances (Section Teratogenic Radiation Effects); for these effects a threshold type of dose dependency can be assumed. However, the sensitivity, especially of the developing central nervous system (CNS) in the early fetal period (primarily between the 8th and 15th week of pregnancy), is so high that the principle of avoiding all unnecessary exposure to radiation must be strictly adhered to.

7.5. Radiation Hazards

7.5.1. *Radiation Carcinogenesis*

An unexpected number of leukemias among the survivors of the atomic bombings initiated the largest epidemiological study that was ever carried out. It is a study of about 100 000 survivors that has not yet been terminated. The enhanced number of leukemias suggested that the frequency of other neoplasias may also be increased. It took more than a decade to confirm this assumption. In an analysis of this universe of atomic bomb survivors up to 1985, about 70 of the 140 deaths due to leukemia and about 350 of the 7000 deaths due to cancer are attributed to the irradiation [185].

In the first analyses of the survivors of the atomic bombings, the number of fatal cases of cancer per year was determined and divided by the total number of persons in the study. From this observed total mortality rate, the spontaneous rate, i.e., the corresponding quotient for nonexposed persons, was subtracted. The additional cancer mortality rate or the excess rate determined in this manner is shown in Figure 40. The numbers given on the ordinate can be understood as additional fatal cancers occurring in a group of 10 000 persons exposed to 1 Sv in the year in question. This simple analysis does not involve a distinction in age at the time of irradiation or in sex. Nevertheless, it shows that the distribution with time is completely different for the radiation-induced leukemias and the solid tumors. Additional cases of leukemia were observed only a few years after the exposure to radiation. The leukemia rates returned toward spontaneous rates 20 – 30 years after the exposure. In the case of solid tumors, however, an increase was observed only after a latent period of about 10 years. This enhancement of the tumor rate has then persisted and it still increases.

Figure 40. The radiation-induced increase in the cancer mortality rate in the survivors of the atomic bombings of Hiroshima and Nagasaki [186]. Each point corresponds to the data from four years of observation. The interpolating curves are given to facilitate readability. The data are influenced by the age distribution of the survivors of atomic bombings which changes with time; they can, therefore, not be directly linked to risk estimates.

a) All leukemias; b) All types of cancer excluding leukemias

More accurate results are obtained from a detailed analysis which takes into account not only the dose and the time after irradiation, but also the age at irradiation and the sex. Thus, the most important results of the epidemiological study in Hiroshima and Nagasaki can be represented in relatively simple models. The difference between the *model of relative risk*, that seems to apply to most of the solid tumors, and the *model of absolute risk*, which applies to leukemias, is schematically presented in Figure 41. In the model of relative risk (Fig. 41 A), it is assumed that a single exposure — after a certain latent period of 10 – 15 years — the spontaneous and age-dependent tumor rates by a factor that is a function of the dose. But the enhancement factor depends on the age at the time of irradiation. There is a clear trend of increased sensitivity for exposure at a young age. However, the survivors of the atomic bombings who were irradiated as children have not yet reached the age of high spontaneous cancer rates; the total risk estimates are, therefore, still uncertain. The model of absolute risk (Fig. 41 B) is of quite different nature, it contains the assumption that after exposure to radiation a pronounced wave of additional cases appears within a few years.

Figure 41. Diagram of the cancer mortality according to the models of relative (A)

— · · — · · 1.0 Sv; · · · · 0.3 Sv; ——— spontaneous rateand absolute risk (B)

— · · — · 0.65 Sv; · · · · 0.25 Sv; ——— spontaneous rate

The epidemiological observations made in Hiroshima and Nagasaki refer to relatively high doses of radiation and they are still based on limited observation periods. Risk estimates, however, are based on the entire remaining life expectancy after irradiation and on the much smaller doses which are of importance in radiation protection. Therefore, a two-fold extrapolation in time and in dose is required. The absolute risk model for leukemias and the relative risk model for solid tumors, as shown in Figure 41, form the basis for the extrapolation [183], [187], [188]. More recent evaluations do not assume simple proportionality in the extrapolation to low doses, but postulate a further reduction factor of 2 [183]. This reduction is not supported by epidemiological observations on humans, but only by the results of animal experiments. On the other hand, the application of the relative risk model would provide an overestimate of the risk, if the relative increases of tumor mortality do not persist over the entire life. Thus, the risk estimates can be regarded as realistic; the extrapolations to longer periods after radiation exposure could be an overestimation while the assumption of the reduction factor could be an underestimation.

The risk estimates for small doses given by the International Commission for Radiological Protection (ICRP) for the different types of tumors are presented in Table 8 [183]. The total risk associated with cancer mortality, i.e., the additional probability of the individual for dying of cancer, is given as 5×10^{-5}mSv^{-1}.

Table 8. Estimated additional probability of the occurrence of a fatal cancer for various tissues and organs. The estimates include a reduction factor of 2 for the extrapolation of the observations on high doses to low doses [183].

Tissue or organ	Estimated additional probability of the occurrence of a fatal cancer (10^{-7} mSv^{-1})
Bladder	30
Bone marrow	50
Bone surface	5
Breast	20
Colon	85
Liver	15
Lung	85
Esophagus	30
Ovaries	10
Skin	2
Stomach	110
Thyroid	8
Other organs	50
Total	500

The observations on the survivors of the atomic bombings are supplemented, and to a substantial extent confirmed, by observations on patients who were exposed to radiation internally or externally for *medical diagnosis or therapy.*

The radiopaque medium thorotrast, which was used in X-ray diagnostics in Germany and Japan up to the 1950s, had disastrous consequences. The quality of the radiopaque medium was based on the fact that it contained the long-lived radionuclide ^{232}Th an element with a high atomic number. It was not sufficiently accounted for that thorium, an α emitter and precursor of ^{226}Ra, represents a radiation risk. The long-term effects were serious [181], [183]. The rates of tumors, and especially of live tumors in the patients who had received thorotrast injection, increased and continued to increase decades after.

Serious long-term effects were also observed in patients suffering from Morbus Bechterew, an inflammatory process of the bone surface, and in young patients with bone tuberculosis who were injected with high activities of ^{224}Ra, a short lived α emitter, in a German sanatorium after World War II. Of the 800 patients who were observed epidemiologically, more than 50 died of bone tumors which appeared up to 20 – 30 years later [189], [190].

Most of the studies are based on relatively high doses. However, the prenatal X-ray diagnostics that was routinely applied up to about 1960 and that resulted in an exposure of the fetus of 10 – 20 mSv represents an exception. The rates of

leukemia in these children were increased by 20 % above the normal values [191], [192].

Further important observations were made on *uranium miners* who inhaled increased concentrations of radon and its decay products for years and showed greatly increased rates of bronchial cancers. The observations made on the uranium miners were used to estimate the risk from radon in houses. Radon, with its α-emitting decay products, represents the largest, although greatly fluctuating, contribution to natural radiation exposure.

7.5.2. *Hereditary Radiation Effects*

Until now, no statistically significant increase in hereditary abnormalities has been detected in human beings as a result of ionizing radiation. This also applies to the extensive observations on the descendants of those who survived the atomic bombings of Hiroshima and Nagasaki. However, it follows from animal experiments that ionizing radiation causes heritable defects also in humans. In the absence of direct data, the estimation of the genetic risk from radiation in human populations must be obtained by extrapolation from the results of the animal experiments. These experiments which were mostly carried out on mice, indicate that a radiation dose of 1 Sv produces about the same number of genetic defects as would normally appear spontaneously in one generation. This is referred to as a *doubling dose* of 1 Sv [187]. Although no increases could be recognized there, this estimate is consistent with the limits of uncertainty of the observations among the survivors of the atomic bombings of Hiroshima and Nagasaki.

7.5.3. *Teratogenic Radiation Effects*

Prenatal irradiation can lead to developmental disturbances and organ deformities. The type and degree of these *teratogenic defects* depend in a complex manner on the phase of the embryonal or fetal development in which irradiation takes place.

Severe deformities can occur after exposure to high doses during the *embryonal period* (9th to 60th day after conception). Animal studies have indicated that a threshold dose exists for this type of damage which is substantially higher than 0.1 Sv [183]. After irradiation during the *fetal period* (from the 60th day after conception) the development of the fetus can slow down. Observations on children who were subjected to prenatal irradiation as a result of the atomic bombings of Hiroshima and Nagasaki have shown that the CNS is an especially critical organ. Developmental disturbances with pronounced morphological alterations have been observed; the clinical expression can range from a reduction in the motor and intellectual capacities (below-average IQ) to severe mental disability and microcephaly. The developing CNS is most radiation-sensitive between the 8th and 15th week of pregnancy. Even low doses carry an increased risk, but a threshold value in the order of 0.1 Sv is assumed for this phase with regard to severe developmental disturbance in the CNS [183].

Besides this deterministic damage, prenatal irradiation can also increase the risk of stochastic effects, such as leukemia and, possibly, other tumors. The use of diagnostic X-rays during pregnancy is, thus, justifiable only in exceptional cases with especially important indications. On the other hand, if the fetus has been exposed to radiation doses less than 0.1 Sv (which is the case in almost all radiodiagnostic examinations), no eugenic indication exists from a radiobiological point of view for the termination of pregnancy.

7.6. Radionuclides

In contrast to radiation exposure the outside, i.e., due to a source of radiation outside the body, radiation exposure from the inside refers to the condition in which radioactive substances are incorporated with food, water, air, or through the intact skin or wounds. In the case of some radionuclides, e.g., the two isotopes ^{134}Cs and ^{137}Cs, incorporation can lead to approximately homogeneous exposure of the whole body from the inside, because the nuclide is uniformly distributed. Many radionuclides are, however, inhomogeneously distributed, accumulating in certain molecules, in certain organelles of the cell, in certain groups of cells, and in certain organs. Examples are the accumulation of radioiodine in the thyroid, or the accumulation of so-called “bone seekers” such as strontium or radium in the skeleton or on the bone surfaces.

There is, in principle, no difference between the action of ionizing radiation on the body, whether it arises from external sources or from sources that are incorporated. The γ-rays produce their actions through the electrons released in the body, and the potential effect is therefore merely dependent on these electrons which do not differ for external or internal radiation. Furthermore, there is no principal difference between the β-rays released within the body and those electrons released by γ-rays or X-rays.

The radiation effects are, of course, greatly dependent on the dose, and the dose and its distribution in the different tissues and organs of the body can vary greatly with the type and strength of external or internal radiation sources. The incorporation, the metabolic distribution and retention, and the excretion of radionuclides are complex factors that need to be accounted for in the dosimetry of internal radiation sources. A further complexity arises from the fact that heavy radioisotopes, such as americium, plutonium, radium, and the ubiquitous radon and its daughter products are α emitters (short ranges of only a few centimeters in air and only ca. 0.05 mm in tissue, see Section Physical Radiation Effects). Their action is therefore only of concern if they are inhaled, ingested, or otherwise taken up by the body. However, in these cases they are particularly effective because they are densely ionizing (see Section Physical Radiation Effects).

7.6.1. *Radionuclides of Concern in Radiation Protection*

A multitude of radionuclides are used in medicine, in industry, and in research. Typical examples indicate the range of their different characteristics and their possible effects. The effects of the α-emitting radionuclides thorium ($t_{1/2}$: 1.4×10^{10} a) and radium (^{226}Ra $t_{1/2}$: 6000 a; ^{224}Ra $t_{1/2}$: 3.6 d) have already been mentioned (see Section Radiation Carcinogenesis). Even heavier elements have become of concern in the meantime. Examples are the artificially-produced elements americium and plutonium; they, too, are α-emitters. Although these radionuclides have been accidentally incorporated in certain instances, their biological effects, and especially the induction of bone tumors or lung tumors, have been seen only in animal experiments.

Various radioisotopes have been used and are still being used for diagnostic and therapeutic purposes in nuclear medicine. The most important example is the β emitter ^{131}I ($t_{1/2}$: 8 d). In the past it was used for thyroid diagnostics. This produced relatively high doses of about 0.5 Gy to the thyroid, and iodine has therefore been replaced for this purpose by the short-lived ^{99m}Tc (half-life: 6 h, see Chap. Production of Artificial Radionuclides). For the radiotherapy of thyroid cancer the application of high activities of ^{131}I is still the method of choice.

7.6.2. *Exposure of the Population due to Natural and Artificial Radioisotopes*

^{222}Rn and ^{220}Rn are the daughter products of ^{226}Ra and ^{224}Ra, respectively. Depending on the geological characteristics of the soil, these gaseous radionuclides are present in greatly varying concentrations. In underground mines and especially in uranium mines, radon and its α-emitting short-lived daughter products are the major health hazard, and a number of studies [183] have demonstrated strikingly enhanced lung cancer frequencies in underground miners. Radon is also the main contributor to the *natural radiation exposure* of the population, although it affects predominantly only the lung. It is estimated that up to 5 % of all lung cancer cases may be due to radon in houses [187].

A far less important contribution to the natural radiation exposure is that of the extremely long-lived ^{40}K which is present in the human body. Its specific activity is about 60 Bq/kg, and it causes a dose of approximately 0.1 μGy per year [188].

Artificial radioactivity has become notable as a cause of the exposure of large populations due to the atomic bomb tests and reactor accidents. The nuclear bomb tests produced a wide spectrum of fission products, and since these were dispersed at high altitudes and transported over large distances, only the long-lived nuclides were significant contributors to the dose. To indicate the broad spectrum of relevant radionuclides, Table 9 gives the effective doses to the population of the Northern Hemisphere that are caused due to the fallout from weapons by the main fission products.

Table 9. Effective doses to the population of the Northern Hemisphere due to the fall-out of the atomic bomb tests between 1945 and 1980 [193]

Nuclide	Half-life	Inhalation, 10^{-2} mSv	Ingestion, 10^{-2} mSv	External radiation, 10^{-2} mSv	Total, 10^{-2} mSv
^{3}H	12.3 a	0.4	4.7		5.1
^{14}C	5730 a		18		18
^{90}Sr	28.6 a	1.4	17		18.4
^{95}Zr	64 d			29	29
^{103}Ru	39.4 d			2.5	2.5
^{106}Ru	1 a	4.9		8.7	13.6
^{131}I	8 d		4.8		4.8
^{137}Cs	30.2 a		28	60	88
^{140}Ba	12.8 d			3.7	3.7
^{144}Ce	284 d	6.0		2.8	8.8
^{239}Pu	24 100 a	4.0	0.3		4.3
^{240}Pu	6 578 a	2.6	0.2		2.8
^{241}Pu	14.4 a	1.4			1.4
All nuclides		22	78	110	210

The major population exposure due to *nuclear accidents* occurred after the catastrophe of Chernobyl in 1986. In this accident the release of plutonium was largely confined to the close vicinity of the reactor. It was not, therefore, of major concern in the overall picture. The important contributors to the dose were, on the one hand, the short-lived radioiodine and, on the other hand, the long-lived cesium (^{134}Cs: $t_{1/2}$ 2.1 a, ^{137}Cs: $t_{1/2}$ 30 a) and strontium (^{90}Sr: $t_{1/2}$ 28 a).

Radioiodine, and predominantly the isotope ^{131}I, were of major concern immediately after the accident. In the contaminated territories of the former Soviet Union large activities of iodine were ingested with milk and vegetables, and it now appears that more than hundred thyroid cancers in children in Belarus alone have arisen within a few years, beginning from three to four years after the accident. In the Western European countries, the radioiodine has also been of concern after the accident, but the concentrations were lower than in the former Soviet Union and measures had been taken immediately after the accident, to block the use of contaminated milk and vegetables.

The nuclide of lasting consequence after the reactor accident has been ^{137}Cs. With its γ-rays, it acts as an external source of exposure and, both with its γ-rays and β-rays, it contributes to the exposure when it is incorporated through the food chain (see Table 10).

Table 10. Effective doses produced by the ingestion with food of 1 kBq of the long-lived radionuclides that were of main concern after the accident of Chernobyl [193] [a]

Nuclide	Effective dose by ingestion of 1 kBq, 10^{-2} mSv	Total dose in 50 years due to contaminated food, 10^{-2} mSv [b]	
		By deposition of 1 kBq/m^2	By deposition after the Chernobyl accident in the north of Munich
^{137}Cs	1.4	0.9 [d]	59.0
		2.2 [e]	
^{134}Cs	2.0	0.1 [d]	4.0
		0.3 [e]	
^{90}Sr	3.5 [b]	5.4 [d]	1.2
		0.7 [e]	

[a] The doses are given that result over a period of 50 years from the use of products in a region that is contaminated with a surface specific activity of 1 kBq/m^2.
[b] The last column gives the doses that result in this way in a region subject to the same contamination that occurred in the north of Munich after the Chernobyl accident [194].
[c] 39×10^{-2} mSv bone surface; 17×10^{-2} mSv bone marrow.
[d] Food derived from plants.
[e] Food derived from animals.

Strontium is of considerable concern after a reactor accident because it is a bone seeker that can specifically contribute to the exposure of the bone marrow and thereby produce leukemias. It is also difficult to measure; it is a pure β emitter with no accompanying γ-rays. After the accident of Chernobyl the release of strontium has been less important even in the vicinity of the reactor than cesium. However, there have been earlier nuclear contaminations where strontium was the main contributor to the population dose. The most important example is the lasting contamination of the river Techa near the city of Cheliabinsk that occurred when the first nuclear bombs were produced in the former Soviet Union. The follow-up of health effects among the exposed population has shown a definite increase of leukemias [195].

7.7. Basic Principles of Radiation Protection

The basic principle for limiting the risk of stochastic radiation effects, i.e., hereditary damage and cancers, is the reduction of unnecessary radiation exposure to a level as low as reasonably achievable (ALARA). Upper limits for radiation exposure have been given as an additional constraint, but not as values to be freely exhausted. According to the latest recommendations of the ICRP [183], the upper limit for whole body exposure in a period of 5 years is 100 mSv, and a value of 50 mSv must not be exceeded in one calendar year.

Since the body is not always exposed uniformly, the ICRP has introduced the concept of the *effective dose, E.* This concept permits the comparative evaluation of an inhomogeneous irradiation of the body. The effective dose is obtained from the dose equivalents (see Section Physical Radiation Effects) for the different tissues and organs (H_T) of a person who is partially or completely exposed to radiation. These dose equivalents are the mean values for the particular organs or tissue. Since the radiation-induced risk is not the same for different tissues or organs, the corresponding equivalent doses are multiplied by the *tissue weighting factors,* w_T (Table 11) and the products are then summed up for all the tissues and organs of the body:

$$E = \sum_T w_T \cdot H_T \tag{7.2}$$

As in the case of the dose equivalent, the effective dose is expressed in sievert.

Table 11. Tissue weighting factors for the calculation of the effective dose [183]

Tissue or organ	Tissue weighting factor, w_T
Gonads	0.20
Bone marrow	0.12
Colon	0.12
Lung	0.12
Stomach	0.12
Bladder	0.05
Breast	0.05
Liver	0.05
Esophagus	0.05
Thyroid	0.05

Skin	0.01
Bone surface	0.01
Other organs or tissue	0.05

The sum of the weighting factors for all the tissues and organs of the body is 1. This means that in the case of homogeneous exposure of the whole body, in which the equivalent doses for all the tissues and organs are the same, the effective dose is equal to the dose equivalent. If only one organ is irradiated, the effective dose is less than the dose equivalent in this organ. To give an example, if only the thyroid gland is exposed, the effective dose is 1/20 of the dose equivalent in the thyroid (Table 9).

The dose limits mentioned above apply to the effective dose, i.e., there is an upper limit of 100 mSv in a 5 year period and 50 mSv in one year. According to the present law in Germany [196], [197], the limit of the lifetime dose from exposure in an occupation is 400 mSv.

Exposure to low doses is the primary concern of radiation protection. The concept of the effective dose and the tissue weighting factors refers, therefore, to stochastic effects (malignant diseases, hereditary defects in descendants). However, the limiting values for the effective dose are sufficiently low, that even in the case of inhomogeneous irradiation of the body, the dose equivalents for any organ remain below the threshold values for deterministic damage (acute or chronic damage). Such damage can generally be excluded within the limiting values. Exceptions to this rule are the lens of the eye and the skin. Radiation can produce deterministic damage (cataracts) in the lens of the eye. The skin can be irradiated very inhomogeneously, and the limitation of the average dose can, therefore, not exclude deterministic effect from a local over-exposure. For these reasons, it is also required that the annual dose equivalent does not exceed 150 mSv for the lenses of the eye and 500 mSv for the skin (taken as an average over 1 cm^2).

The laws governing radiation protection and X-rays in Germany [196], [197] go beyond the recommendations of the ICRP in several areas, especially in the regulations concerning young people, pregnant women, and nursing mothers. For instance, pregnant women must not work in control areas, and nursing women must not come into contact with open radioactive substances.

To protect the population, the laws on radiation protection stipulate that facilities are to be planned and operated in such a way that they never contribute to any member of the public, more than 0.3 mSv per year to the effective dose through the discharge to air or water of radioac-tive substances. The corresponding value proposed by the ICRP is 1 mSv per year.

1. Introduction

General Principles. The clinical use of X-rays for diagnosis (roentgenography) began immediately after the discovery of X-rays by Conrad Wilhelm Röntgen in 1895. This new tool was first used for the diagnosis of foreign bodies, fractures, and diseases of the thorax. Air-containing lung tissues, soft parts of the body (e.g., the heart), and bones differ from the surrounding tissues in their X-ray absorbing properties. This allows differentiation of tissue types on the basis of differences in the blackening of a photographic film. X-ray contrast media can alter the radiolucency; they may be either "negative" or "positive".

Negative X-ray contrast media are gaseous substances that absorb X-rays less strongly than the surrounding body tissues. In contrast to positive media, which produce shadows, negative media darken the X-ray film.

Positive contrast media include water-soluble and oil-based substances, as well as suspensions. The development of strongly absorbing positive X-ray contrast media has allowed the visualization of organs and organ systems consisting of radiolucent tissue, such as the gastrointestinal tract, the urinary and biliary tracts, the blood vessels (peripheral, cardiac, and encephalic), the lymph nodes, the lymph vessels, and the bronchi (morphological diagnostics). In addition, some physiological and pathological processes can also be recognized, for example renal function, perfusion of blood vessels and organs, and the permeability of capillaries, e.g., in the brain (functional diagnostics). In some cases, the physiological functions of the organism are also utilized, for example, intravenous adminstration of contrast media for imaging the urinary and biliary tracts, and oral administration for imaging the biliary tract. After intravasal injection or oral absorption, X-ray contrast media, are excreted by the liver and/or kidneys.

More recently, the development of X-ray contrast media has led to the synthesis of nonionic agents of low osmolarity. At the same time a great deal of progress has been achieved in technology. One example is the continued development of computerized tomography and subtraction techniques leading to considerable enhancement of contrast.

Physical Principles. Substances that are suitable for use as positive X-ray contrast media (radiopaque media) should absorb X-rays more strongly than the body tissue. This depends primarily on the mass absorption coefficient of an element at the X-ray wavelengths used for diagnosis. Elements with medium atomic numbers of 50 – 60 (iodine, barium, lanthanum, cerium) are especially suitable; those with high atomic numbers (mercury, lead, bismuth, thorium) are less appropriate.

When a parallel beam of X-rays of wavelength λ passes through a layer of material with thickness d cm and density ρ g/cm^3, the absorption of monoenergetic X-rays is described by the attenuation formula $J = J_0 e^{\mu d}$, where J_0 is the intensity of the radiation in front of the layer, J is the intensity behind the layer, and μ is the linear absorption coefficient. The mass attenuation coefficient is defined as μ/ρ; it varies with the energy of the radiation and with the atomic

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_593

number of the element in the material through which the radiation passes. The attenuation formula thus becomes $J = J_0 e^{\mu m/\rho}$, where m denotes the mass of material in grams per square centimeter of surface area normal to the propagation direction. Figure 1 shows X-ray absorption as a function of the X-ray energy.

Types of Contrast Media (Fig. 2). Negative contrast media are weakly absorbing substances and include gases that are inert, readily soluble in blood, and quickly eliminated (e.g., NO, CO_2, air, O_2, and He). In cavities such as the abdominal cavity, joint cavities, or cerebral ventricles, they produce a negative contrast. The contrast difference is, however, slight, so that special techniques have to be used to obtain suitable images.

Figure 1. Absorption of X-rays as a function of X-ray energy
a) Absorption by water (corresponds to soft tissues); b) Absorption by an aqueous solution of a contrast medium containing 20 mg I/mLAn X-ray energy of 50 keV corresponds to a tube voltage of ca. 100 kV.

Positive contrast media are divided into two types, according to whether they contain iodine or not. Iodine-substituted organic compounds are more important in practice. Water-soluble and water-insoluble solids, colloids, and oil-based compounds are also employed.

The first X-ray images of the urinary tract and blood vessels were made in 1900 – 1925 with bismuth and thorium compounds, sodium iodide, sodium bromide, lithium iodide, and iodized oils. Because of their high toxicity, the use of these products remained very limited, however. Roentgenography of the urinary and biliary tracts was given a boost when iodinated organic molecules, such as the tetrasodium salt of tetraiodophenolphthalein, were introduced. The iodopyridones, synthesized by Binz and Räth in 1928, represented milestones in the development of iodine-substituted organic contrast media. After clinical investigation by von Lichtenberg and Swick in 1929,
the sodium salt of 2-oxo-5-iodo-1-pyridineacetic acid was brought on the market in 1930 under the trade name Uroselectan. It was considered the "model" of a physiologically compatible, radiopaque renal contrast medium.

Modern iodine-containing contrast media were developed from 1950 onwards for use in urography, angiography, cholecystography, and cholangiography. These compounds contain a benzene ring with three iodine atoms. They also have a salt-forming carboxyl group attached to their nucleus or side chain.

Table 1. Applications of X-ray contrast media

Application	Organs imaged	Administration
Urography (pyelography)	renal pelvis and ureters	intravenous (excretion urography), by urethral catheter (retrograde urography)
Angiography (venography, arteriography, cardiography)	blood vessels	intravenous, intraarterial
Computerized tomography	brain tumors, ventricular system of the brain	intravenous, intraventricular
	spinal cord, nerve roots	intrathecal
Cholecystography, cholangiography	gall bladder and bile ducts	intravenous, oral
Bronchography	bronchi	instillation
Myelography	canal of the spinal cord	intralumbal injection
Lymphography	lymphatic vessels	intralymphatic injection
Gastrography,	gastrointestinal tract	oral, retrograde
Hysterosalpingography	uterus and fallopian tubes	instillation

Contrast media differ in their side chains and in the types of cations present. It was soon realized that many side effects of angiographic contrast media (e.g., pain, vasodilation, hypotension) were due to the high osmolality of these agents. At the beginning of the 1970s, two contrast media of low osmolarity were synthesized:

Figure 2. Classification of X-ray contrast media

ioxaglate, a monocarboxylic dimer, and metrizamide, a nonionic monomer. Both of these, however, have considerable drawbacks. Ioxaglate causes a higher incidence of some side effects, such as nausea, vomiting, and urticaria; it is viscous on account of its dimeric structure. Metrizamide is unstable in aqueous solution and must be prepared immediately prior to use.

Further developments led to the nonionic contrast media iopamidol, iohexol, and iopromide, which can all be administered directly as stable solutions.

The first blood-isotonic X-ray contrast medium was developed in the 1980s. Iotrolan, a nonionic dimeric compound, is particularly compatible with nerves and tissues.

Virtually the only iodine-free contrast medium still in use is water-insoluble barium sulfate (in gastrointestinal diagnostics).

Applications. Contrast media have a wide range of uses (Table 1), from the imaging of body cavities to the investigation of parenchymatous structures. Despite extensive research, however, only a limited number of suitable chemical compounds are available.

Requirements of Iodine-Containing X-Ray Contrast Media. The following *physical and chemical requirements* apply:

1) The iodine atoms must be tightly bound to the compound to avoid side effects caused by partially deiodized cleavage products or iodine which has been cleaved off in the body. Substances intended for intravasal administration must also be highly stable to withstand heat sterilization of the solutions.
2) To absorb X-rays efficiently in diagnostics, compounds often have to have a high iodine content (50 – 60 wt %).
3) Compounds for intravenous administration (urography, angiography, cholecystography, and cholangiography) must be highly soluble in water. Commercial preparations contain 300 – 850 mg of the contrast material per milliliter of solution. The iodine content is 140 – 380 mg/mL. Ideally, the solutions should be stable and have a low viscosity, a weak osmotic effect, and a neutral pH.
4) Oil-based contrast media (for lymphography) must have a low viscosity.

Physiological and pharmacological requirements are as follows:

1) X-ray contrast media must have very low general and local toxicities (irritant effect) because they are used in higher dosages than other pharmaceuticals. They must have a minimum inherent pharmacodynamic action (e.g., effect on blood pressure or cardiac output) and produce minimal side effects (vertigo, nausea, vomiting, headache).
2) The contrast medium must accumulate quickly and selectively in the organ to be visualized, and must have an adequate residence time. This means that substances administered intravenously or orally must be appropriately eliminated from the organism, i.e., either via the kidneys (urography) or via the liver (cholecystography and cholangiography). In addition to these techniques that involve physiological, functional contrast enhancement, body cavities and blood vessels can also be filled by the direct administration of X-ray contrast media (angiography, bronchography, myelography, lymphography, and gastrography). The requirement for selective accumulation does not apply to these applications.
3) X-ray contrast media must be excreted from the organism rapidly, with as little modification as possible.

Pharmacological Testing of X-Ray Contrast Media. Primary screening is first carried out to assign the medium to one of the indication areas (urography, angiography, cholecystography, cholangiography). The dependence of its absorption on the mode of administration and its elimination characteristics (ratio of excretion by kidneys and in bile) are determined in pharmacokinetic studies (using tracer-labeled sub-stances in rats). A further criterion is the acute toxicity (LD_{50}) after intravenous administration; an $LD_{50} > 12$ g I/kg body weight indicates suitability for urography and angiography; > 5 g I/kg body weight, for cholecystography and cholangiography (intravenous administration); > 0.3 g I/kg body weight, for cholecystography and cholangiography (oral administration). Studies are performed on dogs to compare the medium under test against standard preparations with regard to the sharpness and density of the radiographic contrast, time and duration of imaging, and reproducibility of results; these tests supplement those performed in screening. Other series of trials are carried out to investigate local compatibility (tissue reactions), hemodynamics, and pharmacokinetics. Further studies are designed to provide a more detailed description of the pharmacology (extended hemodynamics, studies of kidney and liver function, vessel tolerance, cerebral tolerance, effect on the hematopoietic system, effect on endogenous metabolism). Toxicity studies are also performed on two animal species for several weeks as required by the health authorities.

2. Urography, Angiography, and Computerized Tomography

Pharmacological Principles. Roentgenographic imaging of the kidneys (pelvis and calices) and urinary tract (ureters and bladder) requires substances whose nephrotropic properties cause them to be excreted quickly via the kidneys after intravenous administration. Urographic contrast media bind only slightly to

proteins. Due to their small size the molecules are effectively filtered by the glomeruli.

The contrast media used for imaging the kidneys can also be employed for angiography and computerized tomography. Computerized tomography is an X-ray imaging technique which produces transsectional pictures of the body. Since the high flow rate in the blood vessels results in rapid dilution, a high concentration and injection volume of the contrast medium is necessary to obtain adequate opacification. The organ and systemic toxicity must therefore be extremely low, local tissue compatibility must be good, and the medium must be as pharmacodynamically inert as possible. Excretion requirements are the same in angiography as in urography.

Preparations (see Table 2).

Ionic Contrast Media. In 1950, WALLINGFORD and coworkers discovered that the sodium salt of *acetrizoic acid* (3-acetamido-2,4,6-triiodobenzoic acid) had a low toxicity, was quite soluble in water, and was excreted in the urine. The compound was introduced in the United States by Mallinckrodt under the trade name Urokon. In 1954, it was replaced by *amidotrizoic acid* (diatrizoic acid) which was independently developed by Schering and Sterling – Winthrop. It offered a lower toxicity and a better neurotoxic and hemodynamic compatibility. Diatrizoate became the world's most widely used contrast medium for urography and angiography. A number of monomeric ionic compounds are derived from diatrizoic acid (e.g., metrizoic acid, iothalamic acid, iodamide, ioxithalamic acid, and ioglicic acid).

Ioxaglate is a monocarboxylic dimer consisting of two triiodobenzene rings connected by a chain. This contrast medium has become important in peripheral angiography because it causes little vessel pain. Despite its low osmolality, however, it does not have the expected general and neural tolerance as compared to nonionic contrast media. The osmolality is just one of the many factors that elicit undesired reactions to contrast media.

Nonionic Contrast Media. The *monomeric nonionic contrast media* (iopamidol, iohexol, iopromide, ioversol, and iopentol, Table 3) exhibit better neural compatibility because they are hydrophilic, do not bear charges, and do not require the presence of cations (sodium, meglumine) to form solutions. They are also less likely to cause general side effects, such as nausea, vomiting, and allergic reactions. In addition, they are largely free of side effects caused by high osmotic pressure (e.g., pain, endothelial injury, disturbance of the blood – brain barrier, thromboses, bradycardia in cardioangiography, and increased pressure in the pulmonary circulation).

The nonionic contrast media differ in osmolality and chemotoxicity. The term chemotoxicity includes various properties of the molecule, such as the ability to liberate histamine from most cells, to influence the complement and coagulation system, to change the erythrocyte shape, and to bind to proteins.

Iotrolan is the first *dimeric nonionic contrast medium.* Being isotonic with cerebrospinal fluid and blood at high iodine concentrations (ca. 300 mg/mL), it offers excellent compatibility with neural tissue, along with good general tolerance. After subarachnoidal injection, only a very small fraction diffuses into the interstitial space of the brain parenchyma. The residence time there is short, so irritation of neural structures is unlikely. The high iodine content of the molecule means that not only the entire subarachnoidal space but also other body cavities can be imaged (arthrography, hysterosalpingography, and endoscopic retrograde cholangiopancreatography). The application has been extended to angiography, urography, and computerized tomography enhancement as well.

Structure – Activity Relationships. All the contrast media used in urography and angiography are based on 2,4,6-triiodobenzoic acid:

The individual structural groups perform special functions. The three iodines with their symmetrical configuration are responsible for the contrast density (a different configuration would make the substances less stable). The carboxyl group forms salts and therefore provides good solubility in water. The substituents R and R^1 also affect solubility but primarily in-

* 370 mg I/mL

fluence toxicity, the rate of renal excretion, and physical parameters such as viscosity and osmotic activity. R must always be an acylamino or acylalkylamino group, whereas R^1 can be acylamino, alkylaminocarbonyl, or acylaminomethyl. These requirements set narrow limits on possible chemical variations, especially as higher acyl and alkyl residues have detrimental effects on tolerance, excretion, viscosity, and circulatory system compatibility.

Nonionic, water-soluble contrast media have the same basic structure, but R and R^1 are usually large, hydrophilic side chains and the carboxyl group is reacted with an amine so that the molecules are electrically neutral in solution.

Synthesis. The starting products for the synthesis of water-soluble X-ray contrast media are iodine and derivatives of 3,5-dinitrobenzoic or 5-nitroisophthalic acid. Ionic contrast media can be prepared in fewer synthesis steps than nonionic ones (see Fig. 3).

3. Cholecystography and Cholangiography

The gall bladder and bile ducts can be imaged by oral and intravenous administration of a hepatotropic X-ray contrast medium. When administered orally, the agent is absorbed in the small intestine. In the pH range of the intestine, some of it is in the undissociated, lipophilic form and can therefore pass through the lipid-containing membranes of the intestinal epithelium into the blood. Bound to plasma proteins, it passes through the portal vein into the liver. Oral contrast media for cholangiography and cholecystography are monomers. They initially lack the higher molecular size needed for biliary excretion but gain it after conjugation with glucuronic acid. After biliary excretion and subsequent partial enteric absorption, the contrast medium is eliminated via the kidneys, primarily in the form of a glucuronide (Fig. 4).

The synthesis of iopodinic acid.

The structural requirements relating to absorption in the small intestine do not apply to contrast media that are administered intravenously. These agents must have good solubility and lower toxicity. Unlike orally administered preparations, an intravenous medium reaches all organs and is then concentrated in the gall bladder by a factor of 30 – 100 after active secretion via the liver cells. From the gall bladder, it passes into the small intestine, and is then eliminated with the feces. There is no enterohepatic circulation because absorption is low. 10 – 20 % of the quantity administered is excreted via the kidneys.

Figure 4. Schematic diagram of absorption and excretion of oral contrast media in cholecystography and cholangiography

Oral Contrast Media. Oral media for cholangiography and cholecystography show a wide range of chemical variation but a high degree of similarity between the individual components. Many of the compounds synthesized can be described by the following formula:

The symmetrical configuration of iodine atoms is responsible for the high contrast density, as in the case of media for uro-angiography (Chap. 2). The carboxyl group aids in the formation of water-soluble salts. The structural element X can be CH_2, O, S, CONH, SO_2, NH, $N(COCH_3)$, H_3C-NHCO, or some other group; this component governs the toxicity and also contributes to the solubility. The performance of these media is determined by the lipophilic aliphatic residue Y. Substituent Z, which can be OH, NH_2, or substituted NH_2, influences the absorption, excretion, and toxicity. Good enteral absorption requires a balance between lipophilic and hydrophilic groups.

Among the many oral contrast media, the following are chiefly used in diagnostics: iopanoic acid, iobenzamic acid, iopodinic acid, and iocetamic acid (Table 4).

Iopanoic acid is excreted with the feces, chiefly in the form of a nonabsorbable glucuronide ester. Iobenzamic acid is excreted mainly with the feces in the form of a metabolite. More than 50 % of iopodinic acid leaves the body via the kidneys, in the form of the glucuronide, whereas iocetamic acid is almost exclusively eliminated via the kidneys.

Intravenous Contrast Media. A key advance in the roentgenographic imaging of the intra- and extrahepatic bile ducts resulted in 1953 when Langecker, Harwart, and Junkmann introduced *iodipamide* [*606-17-7*] [*N,N′*-adipyl-bis(3-amino-2,4,6-triiodobenzoic acid); the methylglucamine salt is marketed under the trade name Biligrafin, Schering AG, Berlin].

Iodipamide

Iodipamide is the prototype of gall bladder and bile-duct contrast media for intravenous administration. It is a dimeric diacid with no side chains in the 5,5′-positions of the triiodobenzoic acid moieties. It is excreted without chemical modification, primarily in the bile.

Iotroxic acid [*51022-74-3*] *and iodoxamic acid* [*31127-82-9*], the modern intravenous contrast media for cholangiography and cholecystography, are less strongly bound to albumin than iodipamide and hence display better tolerance. These contrast media also have a higher affinity for the carrier proteins of the liver cells; they are therefore excreted more quickly into the biliary system while giving a high contrast density.

Table 4. Oral contrast media for cholecystography and cholangiography

Substituents X	Substituents Y	Chemical name, CAS registry no.	Empirical formula	Generic name	Trade name	Company	Year of introduction	LD_{50} (intravenous, rat), g/kg

4. Bronchography

Bronchography is relatively difficult, time-consuming, and uncomfortable for the patient. After local anesthesia, a special catheter is used to introduce the X-ray contrast medium into the bronchial region to be imaged. An optimal medium, with high contrast density, low diffusibility, good adhesion and miscibility with the bronchial secretion, and rapid, quantitative absorption, has not been developed. Trials of a simple, noninvasive inhalation technique for administering the X-ray contrast medium (inhalation bronchography) have been unsuccessful. The reason is that it has not proved possible to generate a well tolerated and highly concentrated aerosol of contrast media powders or solutions.

Bronchography is becoming less popular. It is being replaced by bronchoscopy and less intrusive procedures, such as computerized axial tomography, that often supply more information.

Preparations. For bronchography with a fiber-optic bronchoscope, the nonionic dimer iotrolan-300 (Table 2) is greatly prefered over the previously used contrast medium, dionosil. Iotrolan can be injected directly through the bronchoscope; it does not have a detrimental effect on the bronchoscopic image or on subsequent studies.

5. Myelography

The nonionic dimeric contrast medium iotrolan has been available since 1988, and is very satisfactory for the visualization of the subarachnoidal space (Table 2). The contrast medium can be injected directly, and mixes well with the cerebrospinal fluid. It is isotonic and consequently better tolerated than hypertonic nonionic contrast media. Iotrolan is completely absorbed from the subarachnoidal space and is excreted via the kidneys in chemically unchanged form. Its high iodine content results in better definition of detailed neural structures. Other nonionic contrast media such as iopamidol and iohexol ase also suitable for myelography.

6. Lymphography

Noninvasive techniques – ultrasound and whole-body computerized tomography, (CT) – have largely replaced lymphography, which has been practiced since 1952. Lymphography can image finer structures, so it tends to find use only when uncertain or negative results are obtained.

In order to visualize the lymph nodes, the contrast medium must be slowly injected into an exposed, cannulated lymph vessel using an infusion pump. The lymph nodes in the thorax become visible after ca. 1 – 2 h. A lymph duct can only be detected after the subcutaneous injection of a lymphotropic dye (e.g., methylene blue). The method of "direct lymphography" (intralymphatic injection) is time- consuming and difficult. Efforts to develop "indirect lymphography," with subcutaneous, intramuscular, intracutaneous, or submucosal injection of an X-ray contrast medium, have only yielded limited success because the media studied were not sufficiently lymphotropic.

Contrast media for lymphography must satisfy the same requirements as other substances for endovasal administration (high iodine content, good local compatibility, low toxicity, and low viscosity) and must also have a well-defined retention time in the lymph node. Lymphographic agents must also be quickly and completely excreted, either as such or after degradation. Temporary storage and retention are desirable in media used for lymphography, as opposed to those used for imaging other vessels. These properties are not, however, essential for X-ray contrast media employed in peripheral lymphangiography.

Preparations. All commercially available contrast media for direct lymphography are oil-based substances such as lipiodol (iodized oil). These meet the requirements for a well-defined retention time and good contrast enhancement. They are not, however, fully satisfactory with regard to viscosity, excretion rate, stability, and compatibility. Pulmonary embolisms can easily occur when lymphangiography is carried out with oil-based contrast media because the lymphatic system is connected to the venous system. Water-soluble contrast media have not yet proved successful because the intralymphatically injected media diffuse out of the lymphatic

vessels too quickly and fail to give adequate contrast enhancement, especially of the lymph nodes.

In special cases, lymphatic vessels and local lymph nodes can also be imaged by intracutaneous injection of the water-soluble, nonionic contrast medium iotrolan.

7. Gastrointestinal Contrast Media

Since the early days of roentgenography, barium sulfate has maintained its position as the optimal medium for imaging the gastrointestinal tract. Numerous preparations are available with standardized particle sizes (0.3 – 1 µm). They contain additives (e.g., tragacanth, methyl cellulose, glycerol, mineral oil) to improve the viscosity, adherence, and wetting power and to reduce the sedimentation rate.

There are, however, some risk groups of patients where barium sulfate should not be used (e.g., risk of aspiration or of perforation). Watersoluble X-ray contrast media are also employed for imaging the stomach, duodenum, and colon. An example is diatrizoate, which is available as a 76 % aqueous solution of a sodium – methylglucamine salt mixture, with flavorings and wetting agents (Gastrografin, Schering). If it leaks into the peritoneum, it is readily absorbed and excreted.

Nonionic, water-soluble contrast media are being increasingly employed in gastrointestinal diagnostics because of their good compatibility. Few side effects are produced if the medium passes into the lung or peritoneal cavity. Since these media have a low osmolality they produce much smaller changes in the water and electrolyte balance than do ionic water-soluble agents.

Iotrolan (Isovist-300) is employed in children and, in special cases, in adults. It shows no dilution due to osmotic effects and is the water-soluble contrast medium with the most pleasant taste.

Based on the article Seltene Erden from Ullmann's 4th edition, written by Jaques Helgorsky, Alain Lévêque, Thomas Petzel, and Klaus Reinhardt.

1. Introduction

The metallic elements known collectively as the rare earths (better: rare earth metals or rare earth elements, abbreviated to RE) are listed in Table 1. General reviews are given in [1–6]. Originally, the name was only used for the sesquioxides, RE_2O_3, which are extraordinarily similar to one other in their chemical and physical properties and are therefore difficult to separate. Within the rare earth group, the elements scandium, yttrium, and lanthanum differ in their atomic structure (see Table 2) from the elements

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_607

cerium to lutetium (the lanthanides, Ln). The term lanthanoids has been proposed by IUPAC to include lanthanum and the lanthanides [7], but this usage is not yet universal. In the fields of mineralogy and geochemistry (see Chap. 2), the term cerium earths is used for the elements La and Ce to Eu, and yttrium earths for Y and Gd to Lu. Scandium occupies a special position with respect to this classification and its other properties, and therefore does not belong to either of these groups. The terms terbium earths for Eu, Gd, and Tb; erbium earths for Dy, Ho, Er, and Tm; and ytterbium earths for Yb and Lu are now hardly used. The rare earth elements always occur in nature in association with each other (see Chap. 2). The isolation of groups of rare earth elements or of individual elements requires costly separation and fractionation processes owing to the great similarity of the chemical and physical properties of their compounds (see Chap. 5), which explains why the history of their discovery has extended over such a long period.

The discovery of the rare earths is summarized in Table 3, with the exception of the radioactive element promethium (see Section 3.1). Further details are given in [8]. The word "rare", when used to describe this group of elements, originates from the fact it was thought that the rare earth elements could only be isolated from very rare minerals. Considering the abundance of the rare earth elements in the Earth's crust (Chap. 2), the term rare is inappropriate.

2. Mineralogy, Abundance, Occurrence

The rare earth elements are lithophilic and are therefore concentrated in oxidic compounds such as carbonates, silicates, titanotantaloniobates, and phosphates, or form minerals of these types on their own [6, 9] (see also [1, parts A 4, A 5]). The formation of the minerals is influenced by variations in ionic radii, crystallochemical factors such as coordination number, basicity, potential for isomorphic replacement, tendency to form complexes, and differences in oxidation states [10], (see also [2, vol. 3, pp. 1 – 80]). These factors lead to the division of the rare earth elements into three groups, according to the mineralization process (REO denotes the rare earth sesquioxides):

1) Minerals that contain lanthanum to neodymium, samarium, and europium, and in which cerium and, in some cases also lanthanum or neodymium, are present as the main components (cerium earths, Ce...). Typical examples of this group include bastnaesite (Ce...)FCO_3 (max. 75 % REO content), monazite (Ce...)PO_4 (max. 65 % REO content), and allanite (Ca, Ce...)$_2$(Fe, Al)$_3$ $(SiO_4)_3$(OH) (max. 28 % REO content).
2) Minerals with gadolinium to lutetium and yttrium as main components (yttrium earths, Y...). Typical examples of this group are xenotime (Y...)PO_4 (max. 62 % REO content) and gadolinite (Y...)$_2FeBe_2Si_2O_{10}$ (max. 48 % REO content). Typical compositions of bastnaesite, monazite, and xenotime from various mineral resources are given in Table 4.
3) Complex minerals in which both yttrium earths and cerium earths can be represented in the same mineral type, either of these groups of rare earths being the main one. Minerals of this type are oxidic ores containing titanium, niobium, tantalum, uranium, and thorium; for example:

Euxenite	(Y..., Ce...)(Nb, Ta, Ti)$_2O_6$
Samarskite	(Y..., Ce...)$_4$(Nb, Ta, Ti)$_2O_6$
Fergusonite	(Y...)(Nb, Ti, Ta)O_4
Betafite	(U, Ca, Y..., Ce...)$_2$(Nb, Ta,Ti)$_2O_6$(OH)

The minerals of the first two groups occur in pegmatites and metamorphic gneisses, as well as hydrothermal and pneumatolytic veins, and in skarns and carbonatites. The minerals of the third group are mainly found in pegmatites.

Useful concentrations (up to 5 %) of rare earth elements occur in apatite Ca_5(F, Cl, OH)$(PO_4)_3$ (see typical composition in Table 4), and up to 10 % in pyrochlor (Na, Ca, Ce...)$_2$(Nb, Ta, Ti)$_2$(O, OH, F)$_7$, and loparite (Na, Ca, Ce...)$_2$(Nb, Ta, Ti)$_2O_6$ in the Kola Peninsula (CIS), and also in most uranium minerals as trace substituents.

Scandium occurs in trace amounts in most rare earth minerals along with the true rare earth elements (e.g., as a substituent ion of the same valency). However, the amounts are very small. Thortveitite, $Sc_2Si_2O_7$; sterretite, $ScPO_4 \cdot 2 H_2O$; and kolbeckite (Sc, Be, Ca) $(SiO_4, PO_4) \cdot 2$

Table 1. Atomic numbers, relative atomic masses, and natural nuclides of the rare earth elements

Element	Symbol	Atomic number	M_r	Mass numbers of the nuclides (abundance in %) ∗
Scandium	Sc	21	44.9559	45 (100)

∗ For Tb^0, possibly also $4f^8\,5d^1\,6s^2$.

H_2O are genuine scandium minerals. Apart from scandium, thortveitite also contains yttrium, ytterbium, and lutetium.

In many minerals, scandium is present in a dispersed state. Wolframite and cassiterite can contain up to 1 % scandium, so that scandium is a byproduct of the production of tungsten and tin. Uranium minerals contain much smaller amounts of scandium, but, since uranium is produced in relatively large quantities, scandium is produced in appreciable quantities also.

The abundance of the rare earth elements taken together is quite considerable. Cerium, the most common rare earth, is more abundant than, e.g., Co. Yttrium is more abundant than, e.g., Pb, whereas genuinely rare REs such as Lu and Tm are as abundant as Sb, Hg, Bi, and Ag. Promethium in rare earth minerals is present only in amounts of $< 10^{-19}$ % as a result of nuclear re-

Table 3. History of the discovery of the rare earth elements [6, 8]

Element	Year	Discoverer	Notes
Scandium	1879	Nilson	from ytterbium earths (De Marignac, 1878)
Yttrium	1843	Mosander	from yttrium earths (Gadolin, 1794)

actions with cosmic rays or the spontaneous fission of ^{238}U.

The rare earth minerals of the three groups referred to above occur in distinct deposits (Fig. 1) [11]. Perhaps the most important mined rare earth deposit is at the Mountain Pass Mine in California (carbonatite), where up to 40 000 t/a bastnaesite ore concentrate (70 % REO) is produced by ore beneficiation. Other important bastnaesite deposits are in Burundi (carbonatite), Madagascar (alkali rock), and in Bayan Obo, near the town of Baotou in Inner Mongolia in the People's Republic of China. The bastnaesite, with monazite, is associated with magnetite – hematite – fluorspar.

Monazite mainly occurs in secondary deposits in the heavy minerals of coastal sands. The extraction of monazite is closely linked with the extraction of rutile, ilmenite, and zircon in Australia, Brazil, India, and the United States, and

with the extraction of cassiterite in Indonesia, Malaysia, Thailand, Nigeria, and Zaire. However, this also means that the amount of monazite available depends on the demand for the main product. These monazites contain up to ca. 10 % thorium. Xenotime is found in similar deposits, Malaysian monazite having particularly high xenotime contents.

Primary monazite deposits with high thorium contents are found in Brazil, and particularly in the Republic of South Africa, though these are not extracted at present. Low-thorium monazites occur in primary carbonatitic deposits in Malawi and Burundi.

The minerals of the third group are extracted mainly for their Nb, Ta, and U contents.

In 1990, world reserves of rare earth minerals were estimated at ca. 84×10^6 t REO. China has estimated reserves of 43×10^6 t REO (ca. 50 % of the world reserves). The Baiyunebo deposit near Baotou in Inner Mongolia is the largest source of rare earth minerals in the world and accounts for over half of the Chinese production. The bastnaesite deposit at Mountain Pass, California, contains an estimated reserve of 4.3×10^6 t REO representing approximately 5 % of world reserves. Total reserves within the United States amount to 12.6×10^6 t REO.

Reserves elsewhere have been estimated as follows: Australia: 5.1×10^6 t REO, India: 2.3×10^6 t REO, Canada: 0.95×10^6 t REO, CIS: 0.45×10^6 t REO, Brazil: 0.28×10^6 t REO, and others, excluding the United States and China, 19.63×10^6 t REO.

The production of bastnaesite concentrate at the Mountain Pass Mine, California reached a peak in 1984 of 25 312 t REO. In 1990, production totalled 22 829 t REO, representing approximately 27 % of world production [12]. Estimated monazite production expressed as rare earth oxide (REO) in 1990 was as follows: Australia: 6500 t, Brazil: 1900 t, India: 2030 t, Malaysia: 1740 t, Republic of South Africa: 1000 t, United States: 2000 t, and the CIS: 1500 t.

Raw material prices in early 1990 for bastnaesite from the United States with 70 % REO was \$ 1.3/lb, reflecting an increased use of cerium oxide in autocatalysts, glass additives, and polishing compounds. From 1988 to 1991, the price of Australian monazite with > 55 % REO was stable between A\$ 800 – 900/t; Malaysian xenotime as 60 % yttrium concentrate costed \$ 32 – 33/kg.

3. Properties

3.1. Properties of the Nuclei

Some naturally occurring nuclides of the rare earth elements are radioactive. Data on types of radioactive decay and half lives are given in Table 1. Radioactive properties of artificial rare earth nuclides are given in [13]. Promethium, Pm, whose occurrence in nature was sought for a long time without success, was first identified with certainty in 1945 by MARINSKY et al. as a radioactive fission product of uranium [14].

So far, 25 relatively short-lived isotopes of Pm are known (longest half life: 17.7 years for $^{145}_{61}$Pm). ERÄMETSÄ [15] isolated traces of $^{145}_{61}$Pm from the rare earth concentrate of an apatite in 1965, and deduced that the abundance of Pm in nature is $< 10^{-19}$ %. The question whether this is produced by natural uranium fission or by the action of cosmic rays on $^{146}_{60}$Nd is the subject of debate.

The very high thermal neutron absorption cross section of several nuclides of Sm, Eu, and Gd is noteworthy.

3.2. Properties of the Atoms and Ions

3.2.1. Electronic Configuration, Position in the Periodic Table

The electronic configurations of neutral, isolated atoms of the rare earth elements in the ground state (Table 2) lead to the following position of the rare earth elements in the periodic table: the elements Sc, Y, and La are the first members of a series of transition elements (d-elements) with the valence electron configuration $ns^2\,(n-1)\,d^{\,1}$ ($n = 4, 5$, or 6). The 14 elements, Ce – Lu, constitute a series of inner transition elements ("f-elements") which must be inserted between La and Hf. These are the lanthanides, with valence electron configurations of the type $6s^{\,2}\,5d^{\,1}\,4f^{\mathrm{n}-1}$ or $6s^2\,4f^{\mathrm{n}}$. Thus, all the rare earth elements belong formally to Group 3 of the Periodic System.

[e] Estimated.

In the neutral atoms, the $5d$ and $4f$ electrons have similar energies. This fact explains the occurrence of the two typical electronic configurations referred to above within the lanthanide series (see Table 2), whereby the configurations $4f^{\,7}$ (half-filled orbital) and $4f^{\,14}$ (completely filled orbital) are preferred owing to the high thermodynamic stability of such states. The irregularity of the configurations of the two elements immediately before the middle and the end of the lanthanide series, Eu and Yb, are characteristic of the neutral atoms and the mono- and divalent ions. However, in the case of the trivalent ions, the $4f$ orbital is filled in a completely regular manner. The energy of the $4f$ orbital decreases with increasing atomic number and increasing ionic charge, so that when the valency is 3+, which is characteristic of the rare earth elements, the $4f$ electrons represent well-defined "inner electrons" that take virtually

no part in chemical bonding due to their proximity to the nucleus and shielding by the $5s^2$ $5p^6$ octet. Therefore, the regular filling of the $4f$ orbital from Ce^{3+} to Lu^{3+} determines the chemical properties, as the resulting electronic configurations resemble those of the rare gases, and lead to the great similarity of the Ln^{3+} compounds to each other, to the corresponding compounds of La^{3+}, Y^{3+}, and, to a limited extent, to those of Sc^{3+}.

The regular filling of the $4f$ orbital is accompanied by a steady reduction in the Ln^{3+} ionic radii (see Table 5, [17–20], and Figure 2) – the so-called lanthanide contraction. This steady shrinkage of the inner electron shell is mainly caused by the incomplete mutual shielding of the $4f$ electrons against the increasing attraction of the nucleus.

Figure 2. Atomic and ionic radii of the rare earth elements

The peculiarities of the electronic structure of the rare earth elements described here lead to periodic changes in some physical and chemical properties of these elements and their compounds in the series La to Lu, while other properties show a steady or nonperiodic change. The typical similarity of the rare earth elements to each other, which is often emphasized, is in essence only exhibited for the nonperiodic properties. Thus, the regular change in the RE^{3+} radii leads to largely nonperiodic changes in properties that depend on ion size, such as solubility, basicity, normal potential, and enthalpy of hydration. Periodic variation in properties can have various causes and cannot be interpreted with certainty in all cases. Typically, maxima or minima occur at Eu and Yb, because they are situated immediately before the $4f$ shell is half filled ($4f^7$) or completely filled ($4f^{14}$) and attempt to achieve these stable configurations. Periodic variations are observed for atomic radii, molecular volumes, melting points, boiling points, and sublimation enthalpies of the elements. A similar periodicity is also observed in some dissociation enthalpies of gaseous molecules REX (X=chalcogenide) due to cer-tain peculiarities in the electronic configurations [16]. Other types of pronounced periodicity occur, e.g., in magnetic moments and colors of the RE^{3+} ions (see Section 3.2.3).

3.2.2. Oxidation States, Atomic and Ionic Radii

The oxidation state 3+ is characteristic for all rare earth elements, both for solid compounds and for solvated ions in various solvents. The oxidation state 2+ can occur in pure solid compounds of Eu, and, to a slightly lesser extent, Yb, due to the higher stability of the configurations $4f^7$ and $4f^{14}$. It is also observed to a very limited extent with Sm and Tm. In aqueous solutions, Eu^{2+} ions are metastable. All the other Ln^{2+} ions react in acidic media as reducing agents:

$$Ln^{2+}\,(aq) + H^+\,(aq) \rightarrow Ln^{3+}\,(aq) + 1/2\,H_2\,(g)$$

The oxidation state 4+ can occur for Ce and Tb, which follow La and Gd respectively, and also to a very limited extent for Pr and Nd. Only the Ce^{4+} ion is metastable in aqueous solution; The other Ln^{4+} ions oxidize water as follows:

$$Ln^{4+}\,(aq) + 1/2\,H_2O\,(liq) \rightarrow Ln^{3+}\,(aq) + H^+\,(aq) + 1/4\,O_2\,(g)$$

The general preference for the oxidation state 3+ in aqueous solution is probably a consequence of the similarity between the hydration

enthalpy and ionization enthalpy of the ions. The standard electrode potentials listed in Table 6 [8] illustrate the behavior of the various RE^{n+} ions in aqueous solution, and show that the rare earths are a group of highly nonnoble elements. Figure 2 shows the atomic radii (in the metallic state) and ionic radii for the various typical valencies. The periodicity of the atomic radii described above (maxima for Eu and Yb) shows that in the metallic state these elements contribute only two electrons to the bond, so that their atomic volumes are similar to those of the alkaline earth metals. The radii of the Ln^{2+} ions, plus the radius of the Ba^{2+} ion, give a curve resembling the lanthanide contraction curve, and the term baride contraction has been suggested to describe this [21]. The radii of Eu^{2+} and Sr^{2+} are similar, as are the radii of Yb^{2+} and Ca^{2+}, which explains the commonly observed isomorphic replacement of alkaline earth ions by Ln^{2+} ions of similar size.

Table 6. Standard electrode potentials E^0_{298} of the rare earth elements in volts [8] (much of the data is estimated)

Element	RE (s)/ RE^{3+} (aq)	RE^{2+} (aq)/ RE^{3+} (aq)	RE^{3+} (aq)/ RE^{4+} (aq)
Sc	+2.077		
Y	+2.372		
La	+2.522		
Ce	+2.483		−1.74
Pr	+2.462	ca.	−2.86
Nd	+2.431		
Pm	+2.423		
Sm	+2.414	+1.55	
Eu	+2.407	+0.43	
Gd	+2.397		
Tb	+2.391		−1.28
Dy	+2.353		
Ho	+2.319		
Er	+2.296		
Tm	+2.278		
Yb	+2.267	+1.15	
Lu	+2.255		

The similarity of the chemical properties of Ln^{3+} compounds to those of the corresponding compounds of La^{3+} and Y^{3+} can be explained by the similarities between the sizes of these ions. Therefore, as expected, in the case of those properties that are mainly determined by ion size, La should be placed near Ce, and Y between Ho and Er. However, for scandium, which has a comparatively small radius ($r_{Sc^{3+}} = 0.0730$ nm), there is a greater similarity to the chemistry of aluminum ($r_{Al^{3+}} = 0.0530$ nm) than to that of lutetium ($r_{Lu^{3+}} = 0.0848$ nm).

3.2.3. Magnetic and Spectral Properties

The electronic configurations and spectroscopic terms of the Ln^{3+} ions are largely unaffected by the type of compound in which they are situated, owing to the shielding of the $4f$ electrons from the chemical environment by the $5s^2 p^6$ octet. For these ions, with the exception of Sm^{3+} and Eu^{3+}, it is characteristic that the values of the total spins J applicable to the spectroscopic term of the ground state differ from each other fairly widely (difference at room temperature $> kT$) so that in the ground state practically only one J value is occupied. This peculiarity has interesting consequences for the magnetic properties of these ions. While Sc^{3+}, Y^{3+}, La^{3+}, and Lu^{3+} are diamagnetic due to their closed shells, the remaining Ln^{3+} ions are paramagnetic, (see Figure 3). The double maximum in the curve of permanent magnetic moments can be explained theoretically by the additive behaviour of the spin and orbital moments [3, vol. 1, pp. 310 – 350], [22]. These moments are in opposition for the elements before gadolinium, but additive for the elements that follow it. The magnetic moment of Gd^{3+} is due entirely to the electron spin. The magnetic moments of the Ln^{2+} and Ln^{4+} ions mainly correspond to those of the isoelectronic Ln^{3+}ions. Also, there is a noticeable difference between the magnetic properties of the lanthanides and those of the $3d$ transition elements, which are characterized by paramagnetism mainly due to spin.

Figure 3. Magnetic moments of the RE^{3+} ions at 300 K

The Ln^{3+} ions, with the exception of Ce^{3+} and Yb^{3+}, have very sharp absorption bands

in the visible region and partly in the ultraviolet (Table 7). These bands are caused by $f \rightarrow$ f transitions. Their sharpness is due to the above-mentioned shielding of the $4f$ inner shell, which greatly hinders splitting of the spectroscopic terms by external fields. The colors of the Ln^{3+} ions are given in Table 7 [8]. The sequence of colors in the series La to Gd is almost exactly repeated in the opposite direction in the series Gd to Lu. The ions Ce^{3+} and Yb^{3+} do not absorb in the visible region because an $f \rightarrow$ f transition is not possible for the configurations $4\,f^{\,1}$ and $4\,f^{\,13}$. The broad absorption bands of these ions in the ultraviolet region are due to configuration transitions of the type $4f^{\,n} \rightarrow 4\,f^{\,n-1}\,5\,d$.

In aqueous solution, Eu^{2+} is pale yellow, Sm^{2+} is deep red, and Yb^{2+} is yellow.

Table 7. Colors and main absorption bands of RE^{3+} ions in the range 200 – 1000 nm [8]

Ion	Wavelength, nm	Color
La^{3+}		colorless
Ce^{3+}	210.5, 222.0, 238.0, 252.0	colorless

Tm^{3+}	360.0, 682.5, 780.0	pale green
Yb^{3+}	975.0	colorless
Lu^{3+}		colorless

3.2.4. Bonding, Coordination Numbers

The physical, chemical, and above all structural properties of the rare earth compounds indicate that these elements exhibit mainly ionic bonding.

In solution and in crystalline compounds, the RE^{x+} ions (except Sc^{3+}) generally have coordination numbers > 6 [8]. For scandium compounds, which can also be regarded as homologues of aluminum, coordination numbers > 6 do not occur. In general, the tendency of the lanthanides, including Y and La, to form complexes is smaller than for the d-transition elements, as the shielded $4f$ orbitals are not available for forming the hybrid orbitals that form covalent bonds. Also, the very large size of the Ln^{3+} ions compared with other triply charged cations leads to smaller electrostatic forces of attraction.

3.3. Other Chemical and Physical Properties [1, part B 6], [23]

Reactivity. Apart from Eu, which is very readily oxidized under all conditions, the metals react at room temperature with oxygen or dry air relatively slowly, and in moist air rapidly. At elevated temperatures, all rare earth metals ignite in air and react with most nonmetallic elements. In dilute mineral acids, rapid dissolution takes place with formation of RE^{3+} ions. Like the alkaline earth metals, europium and ytterbium form deep blue, strongly reducing solutions in liquid ammonia.

Crystal Structure. Most of the rare earth metals are polymorphic. At room temperature, Sc, Y, Gd to Tm, and Lu crystallize in the hexagonal close-packed system, and La, Pr, and Nd in the double hexagonal close-packed (La type) system. The metals Ce and Yb crystallize in the face-centered cubic system. Sm is rhombohedral, and Eu body-centered cubic. Whenever the body-centered cubic modification occurs, it is always the stable high-temperature form up to the melting point.

Melting Point. The melting points are in the range 816 °C (Yb) to 1663 °C (Lu), and the boiling points lie between 1194 °C (Yb) and 3512 °C (Pr). Eu and Yb have a certain resemblance to the heavy alkaline earth metals in their melting points, boiling points, and molar volumes. Other physical data are listed in Table 8, 9, [1,2,4].

3.4. Miscibility and Alloying Behavior

If trivalent Eu and Yb and tetravalent Ce and Tb are excluded, the atomic radii from La to Lu differ by only 8 % for coordination number 12, so that in all alloy systems of adjacent rare earth

metals there is complete gap-free miscibility in the liquid state and also in a temperature region close to the solidus curve. The liquidus curves are always continuous, corresponding to the behavior of almost ideal mixtures [24–26].

The mutual effect of atomic radius and electronegativity on the formation of mixed crystals between the rare earth metals and other metals is shown in Figure 4, [27], in which La and Lu are given as examples. The nearby elements (within the inner ellipse), exhibit extensive miscibility in the solid state. At a greater distance (within the outer ellipse), they have limited miscibility with the rare earth elements. Elements outside the ellipses have such large differences that only slight solubility in the solid state can be expected. Thus, all transition elements of the adjacent groups 4 – 8 are soluble to a maximum extent of 1 % in the solid state.

In Figure 5 [2], the compositions of intermetallic compounds between various elements and the rare earth metals are shown. The vertical lines show the region in which intermetallic phases exist, while the horizontal lines show the phases themselves. The most important of these are the phases REX_2, REX, and REX_3. The phase containing the highest proportion of rare earth metal is RE_3X. There is no lower limit; for example, a compound REB_{66} is known (see also [28–31]).

3.5. Mechanical Workability

When casting rare earth metals in molds, they must be melted in crucibles made of materials with which they do not react. Depending on the purity required, tantalum, molybdenum, clay/graphite, graphite, or boron nitride, etc. can be used. Inert gas atmospheres, vacuum, or sometimes only a covering salt may also be required. The castings are easily machined by turning, milling, drilling, or sawing, though care must be taken that the pyrophoric character of the metals does not lead to spontaneous ignition of the turnings or powdered material produced. Rare earth metals can easily be extruded at temperatures just below the melting point. The presence of impurities, especially oxygen, has a detrimental effect on cold and hot rolling properties.

4. Digestion of Rare Earth Ores

4.1. Wet Chemical Digestion; Fusion

The most important rare earth minerals monazite, bastnaesite, and xenotime are generally concentrated by physical processes such as heavy medium separation, flotation, and magnetic separation [1, part B 1, pp. 60 – 67]. They are ground to 50 µm – 1 mm and then digested with acids or alkalis. Treatment with alkalies produces the hydroxides of the rare earth metals and thorium, which can then be dissolved in concentrated hydrochloric or nitric acid. Treatment of the ores with sulfuric or hydrochloric acid converts the rare earth metals into soluble sulfates or chlorides [1, part B 1, pp. 67 – 104].

4.1.1. Monazite

Digestion by Alkalis. The reaction of rare earth phosphates with hot, concentrated alkali (50 – 75 %) proceeds as follows:

$$REPO_4 + 3\,NaOH \rightleftharpoons RE(OH)_3 + Na_3PO_4$$
$$Th_3(PO_4)_4 + 12\,NaOH \rightleftharpoons 3\,Th(OH)_4 + 4\,Na_3PO_4$$

This can be carried out at high temperatures in autoclaves (60 % alkali, mass ratio 1 : 1) [32], or with more concentrated alkali at lower temperature (120 °C) and normal pressures [33].

The hydroxides produced are treated with hot water. The trisodium phosphate goes into solution, and the hydroxides are filtered off. The trisodium phosphate, a saleable byproduct, crystallizes out. The washed hydroxides are then dissolved in hydrochloric or nitric acid. If the acid concentration is held at pH 4, a partial separation results, impure thorium hydroxide remaining behind while the rare earth hydroxides dissolve.

Sulfuric Acid Digestion. Monazite can be digested with 98 % sulfuric acid at 200 – 230 °C. The rare earth sulfates formed are then dissolved out of the crystalline, hygroscopic reaction product with cold water. The thorium sulfate either remains undissolved or also goes into solution, depending on the reaction conditions [34].

The dissolved thorium, which was at one time the most important product, was formerly precipitated as sulfate. However, the sharpness of

Figure 4. Darken – Gurry diagram for lanthanum and lutetium [27]

Figure 5. Compositions of binary rare earth alloys [2, vol. 2, chap. 13, pp. 1 – 54]

separation from the rare earth elements was poor. The method now used is to dissolve all the sulfates and separate the thorium by one of the following more effective methods:

1) Precipitation of ThF_4.
2) Precipitation of thorium phosphate by increasing the pH or by dilution.
3) Precipitation of the sodium/cerium earth double sulfates, while the corresponding much more readily soluble salts of thorium and the yttrium earths remain in solution. The thorium is then precipitated by adding oxalic acid, the solubility of thorium oxalate being much lower than that of the oxalates of the yttrium earths. The sparingly soluble double sulfates of the cerium earths are treated with boiling, concentrated alkali solution, forming the hydroxides, which are then dissolved in acid for subsequent fractionation.

4.1.2. Bastnaesite

Digestion with Acids. Many processes have been described for digesting bastnaesite with sulfuric acid. In one of these, the mineral is calcined to decompose the carbonates and then treated with 6 N sulfuric acid to dissolve the rare earth elements as sulfates [35].

In another process, the mineral is slurried with concentrated sulfuric acid and heated to 500 °C. The fluorine is driven off as hydrogen fluoride together with CO_2 and SO_2, and the rare earth elements remain behind as their anhydrous sulfates [36]. These can then be treated like the products from the treatment of monazite with sulfuric acid.

In another process, the mineral is calcined at > 600 °C, and then treated with 16 N nitric acid, which is considerably more effective than 12 N hydrochloric acid or 18 N sulfuric acid [37].

In the Molycorp process , the mineral is concentrated to 60 % by flotation and then calcined, converting the cerium to the tetravalent state. It is then treated with hydrochloric acid, which causes only the trivalent rare earth elements to go into solution, leaving behind 65–80 % CeO_2, which can be converted directly to a glass-polishing material by further calcination [38].

In another process, the carbonates are decomposed by hydrochloric acid. A fluoride residue is obtained, which is treated with alkali. The rare earth hydroxides obtained in this way are used to neutralize the excess acid from the chloride solution [39].

Digestion with Bases. Bastnaesite can be treated with concentrated alkali at ca. 200 °C to form rare earth hydroxides, which are then dissolved in acid [40].

4.1.3. Other Ores

Xenotime is more difficult to digest than monazite. It is usually treated with concentrated alkali, like monazite, but under much more rigorous conditions. Rare earth silicate minerals are best digested with sulfuric acid at fairly high temperatures. Various methods have been described for the extraction of the rare earth elements from apatites during wet production of phosphoric acid [41,42]. A process for the direct treatment of apatite with $NOCl/NO_2/N_2O_4$ at high temperatures is proposed in [43].

In the field of uranium production, only Denisson (Ontario) has so far produced an yttrium concentrate by solvent extraction of a sulfate solution.

4.2. Direct Chlorination at High Temperature

The direct chlorination of rare earth ores in a shaft furnace at 1000–1200 °C produces two groups of chlorides, depending on the impurities present. These are firstly the chlorides volatile at this temperature such as $AlCl_3$, $FeCl_3$, $POCl_3$, $SiCl_4$, $ThCl_4$, $TiCl_4$, $NbOCl_3$, $NbCl_5$, and $TaCl_5$, and secondly the nonvolatile chlorides of the alkali and alkaline earth metals as well as the rare earth chlorides, which collect at the bottom of the chlorinating furnace and are tapped off. The anhydrous rare earth chlorides can be treated, without further drying, by molten salt electrolysis to produce cerium mischmetal or they can be dissolved for further wet chemical processing.

The reaction of bastnaesite or monazite proceeds according to the following equations:

$$3\,REFCO_3 + 3\,C + 3\,Cl_2 \rightarrow 2\,RECl_3 + REF_3 + 3\,CO_2 + 3\,CO$$

$$REPO_4 + 3\,C + 3\,Cl_2 \rightarrow RECl_3 + POCl_3 + 3\,CO$$

The rare earth ore, with a grain size of < 0.2 mm, is pelletized with charcoal powder and a binder. It is then dried and fed into the chlorination furnace (Fig. 6). This consists essentially of a vessel lined with refractory bricks, inside which is a carbon cylinder that is the actual reaction space. A perforated graphite tube located inside this carbon cylinder contains a bed of coke through which the chlorine gas is passed to ensure even distribution before it passes through the solid feed material. The reaction is energetically self-sustaining, and only requires sufficient resistance heating to compensate for radiation losses. The rare earth chlorides collect in the melt space and are tapped off from time to time. A total of ca. 400 t rare earth chlorides can be produced during the working life of the carbon cylinder. The cylinder can be

replaced without difficulty while hot. The output of a chlorination furnace of this type is ca. 100 t/month. The lining of the chlorination furnace has a lifetime corresponding to a total output of 1500 t rare earth chloride.

Figure 6. Diagram of a chlorination furnace [44,45]

The chlorination furnace operates at a slight underpressure. The waste gases are passed into a combustion chamber, oxidized, and washed with alkali to remove residual chlorine. In principle, it is possible to recover the volatile chlorides of valuable elements from the off-gas stream (e.g., $POCl_3$, $NbCl_5$, $TiCl_4$, $TaCl_5$, $ThCl_4$, UCl_4).

5. Separation

The separation of the rare earth elements poses one of the most difficult problems in inorganic chemistry. Due to the great similarity of the chemical properties, the methods are generally not very selective. In a few cases, much better separation can be achieved by conversion to another oxidation state of adequate stability ($Ce^{3+} \rightarrow Ce^{4+}$, $Eu^{3+} \rightarrow Eu^{2+}$).

A further difficulty is presented by the unfavorable distribution of concentrations of individual rare earth metals in the common minerals. The method of separation must therefore be selected to suit the existing ratios. The first step is a preliminary separation into groups of elements that resemble each other very closely.

5.1. Principles of Separation

Two principal types of process are used for the extraction of rare earth elements:

1) Solid – liquid systems using fractional precipitation or crystallization, or ion exchange. Ion exchange processes are used in the production of small quantities of higher value heavy rare earth elements.
2) Liquid – liquid systems using solvent extraction. This process is the most commonly used commercial process for the extraction of rare earth elements.

The distribution of two rare earth elements RE_A and RE_B between the two phases is given by the equilibrium constants k_A and k_B:

$$k_A = \frac{[RE_A]}{[RE_A]} \text{ and } k_B = \frac{[RE_B]}{[RE_B]}$$

where [RE] and [RE] represent the concentrations in the aqueous and nonaqueous phase, respectively. The selectivity of this separation system is given by the separation factor α_{RE_B/RE_A}, where

$$\alpha_{REB/RE_A} = k_B/k_A$$

More correctly, activities should be used instead of concentrations. In practice, apparent equilibrium constants based on concentrations are adequate. In the following discussion, these apparent constants are used throughout.

The processes of fractional crystallization or fractional precipitation are now mainly of historic interest only. The separation factor corresponds to the solubility ratio of the two rare earth elements in the aqueous phase.

In the case of ion exchange or liquid – liquid extraction, the ratio of the distribution coefficients is a measure of the different affinities of the rare earth metals for the two phases.

For the trivalent ions of neighboring rare earth elements, the separation factor is low for all methods. For precipitation or crystallization, $\alpha = 1.1$ to 5; for separation by ion exchange with addition of complexing agents, $\alpha = 1.1$ to 10; for liquid – liquid extraction, $\alpha = 1.1$ to 5.

For an effective separation, many repetitions of a single separation operation are necessary, which can be carried out batchwise or continuously.

With ion exchange separation, although the establishment of equilibrium is continually repeated, the overall process is discontinuous, since continuous feeding is not possible. However, it has the advantage that several rare earth elements can be separated at the same time.

A fully continuous liquid – liquid extraction process in countercurrent flow with partial recycle enables separation to be achieved into two groups or two individual rare earth elements of high purity. The production of three pure rare earth elements requires two batteries of separation equipment. This limitation is, however, compensated for by the advantage of continuous operation.

A further characteristic of a separation process is the size of the apparatus required. This depends on the concentration of the rare earth elements in the two phases. Cationic ion exchangers have a high capacity (ca. 150 g REO/L), but elution in the presence of complexing agents requires very dilute solutions (ca. 5 – 10 g REO/L). These separation plants are therefore very bulky.

In the liquid – liquid extraction process, the capacity of the solvent can be very high (170 – 190 g REO/L), and it is therefore often possible to work with aqueous solutions with concentrations of 100 – 140 g REO/L, i.e., approaching saturation. The equipment is therefore compact.

5.2. Separation by Classical Methods [1, part B 2], [3, vol. 1, pp. 30 – 61], [6]

5.2.1. Fractional Crystallization

Fractional crystallization was the first process for separating the rare earth elements, both in the laboratory and on the industrial scale. It is no longer of importance.

The purification effect decreases with increasing purity of the crystals. The achievable purity is therefore limited. Also, many intermediate fractions are produced that must be reprocessed.

In general, this process is more problematical for the yttrium earths than the cerium earths. The cerium earths were therefore separated by fractional crystallization and the yttrium earths by ion exchange. The cerium earths were converted to nitrates after oxidation of the cerium to the tetravalent state, and the double nitrates $NH_4NO_3 \cdot RE(NO_3)_3 \cdot 4\,H_2O$ were crystallized. Pechiney Saint Gobain produced 99.9 % pure lanthanum in five crystallization stages, this salt being the most soluble. The yttrium was first precipitated as the double chromate and then purified by ion exchange.

5.2.2. Fractional Precipitation

Fractional precipitation was only used for separating the rare earth elements into groups, due to filtration difficulties and the slow establishment of equilibrium.

The best known example is the precipitation of the hydroxides, which enables separation into three groups: (1) yttrium, (2) praseodymium, neodymium, and samarium, and (3) a fraction enriched in lanthanum and cerium.

Another process is the precipitation of double sulfates, $Na_2SO_4 \cdot RE_2(SO_4)_3$. The greater solubility of the yttrium earths enables a crude separation from the cerium earths to be carried out.

5.2.3. Separations Based on Oxidation State Changes

Cerium (IV) or europium (II) can be economically separated from the other rare earth metals by precipitation, ion exchange, or liquid – liquid extraction.

Cerium can be oxidized by oxidizing agents such as hypochlorite, H_2O_2, atmospheric oxygen, or electrolytically at a suitable pH, precipitating it as cerium(IV) oxide hydrate. By adding chlorine and sodium hydroxide solution to a

solution of cerium earth chlorides, cerium(IV) oxide hydrate is precipitated. This can be converted to a 90 % pure cerium oxide that is suitable for use as a polishing material. The separation of tetravalent cerium from the trivalent rare earth elements by liquid – liquid extraction is described in 5.4.2.2.

Divalent europium has properties similar to those of the alkaline earths, especially strontium (insoluble sulfate, soluble hydroxide, etc.). The rare earth metals are usually reduced in hydrochloric acid solution by zinc amalgam or sodium amalgam. The subsequent precipitation of europium sulfate from the very dilute solution can be improved by coprecipitation of strontium or barium sulfate. The europium can be further purified by precipitating trivalent elements as their hydroxides by using ammonia. Under these conditions, Eu^{2+} remains in solution [46]. The separation of divalent europium from the trivalent rare earth elements by liquid – liquid extraction is described in 5.4.3.1.

5.3. Separation by Ion Exchange

This process is based on work carried out on the separation of rare earth elements produced by uranium fission, and formed part of the Manhattan Project (1943 – 1947). The principles of separation by elution were developed by Boyd and coworkers in the Oak Ridge National Laboratory. The Ames Laboratory, Iowa State University, under the leadership of Spedding, investigated the production of rare earth metals on a large scale by displacement elution. Spedding and Powell have provided review of the developments up to 1950 [5, pp. 55 – 73], [47]. Attempts to develop ion exchange column chromatography into a continuous process was realized with the development of the continuous annular chromatograph (CAC) by researchers at Oak Ridge Laboratory in the mid 1970s. However, the process was designed for analytical requirements with low loading of the columns and was therefore not commercialized [48–50]. A more recent development, known as continuous displacement chromatography (CDC) [51], shows greater promise for surpassing present industrial, batch, fixed-column displacement ion exchange processes.

5.3.1. Ion Exchange with Chelating Agents

Sulfonated polystyrene ion exchange resins, which possess high chemical stability, can combine with 0.5 – 0.8 mol of rare earth elements per 1 mol resin. However, differences in the affinities of the rare earth elements for the resin are very small, and the separation factor for two neighboring rare earth elements is only ca. 1.08 [52]. However, this can be considerably improved by the addition of chelating agents.

The separation factor $F_{\mathrm{RE_B/RE_A}}$ for two rare earth elements $\mathrm{RE_A}$ and $\mathrm{RE_B}$ between an aqueous solution and the cation exchanger (concentrations marked with a bar) is

$$F_{\mathrm{REB/RE_A}} = \frac{\left[\overline{\mathrm{RE_B^{3+}}}\right] \cdot \left[\mathrm{RE_A^{3+}}\right]}{\left[\overline{\mathrm{RE_A^{3+}}}\right] \cdot \left[\mathrm{RE_B^{3+}}\right]}$$

On the addition of a chelating agent L, the equilibrium constants in solution are given by:

$$K_{\mathrm{A}} = \frac{[\mathrm{RE_A L}]}{[\mathrm{RE_A L}] \cdot [\mathrm{L}]} \quad K_{\mathrm{B}} = \frac{[\mathrm{RE_B L}]}{[\mathrm{RE_B L}] \cdot [\mathrm{L}]}$$

The constants depend on conditions in the medium, especially the pH of the aqueous phase. For large values of K_{B} and K_{A} and an excess of chelating agent (the concentration of the unchelated rare earth metals then being negligible), a new separation factor $F*_{\mathrm{RE_B/RE_A}}$ can be defined:

$$F^*_{\mathrm{REB/RE_A}} \approx F \cdot \frac{K_{\mathrm{B}}}{K_{\mathrm{A}}}$$

Separation can therefore be much improved by using a chelating agent whose equilibrium constants K_{A} and K_{B} are very different from each other.

Certain carboxylic acids form 1 : 1 chelates over a large pH range with K values that differ considerably for neighboring rare earth elements and which are sufficiently soluble in water. Citric acid is only of historical interest; it was used in the Ames Laboratory to prepare rare earth oxides in kilogram quantities with a purity of 99.9 % in 1947.

Later, polycarboxylic acids were replaced by aminocarboxylic acids, which form chelates with considerably improved stability, selectivity, and solubility.

Figure 7 shows the K values as a function of the atomic numbers of the rare earth elements. They vary between 10^{10} and 10^{20}. The selectivity F_L also varies widely, and can have values of between 1 and 10 for neighboring elements. For ethylenediaminetetraacetic acid (EDTA) and 1,2-diaminocyclohexanetetraacetic acid (DCTA), the selectivity for the cerium earths is much higher than for the yttrium earths. The position of yttrium (dashed lines) varies with the chelating agent over a range from Pr to Dy.

Figure 7. Stability constants K of selected rare earth chelates
– – – – Position of yttrium.

The disadvantage of using chelates is their lower solubility. The most soluble chelates such as those of N-(hydroxyethyl)ethylenediaminetriacetic acid (HEDTA) or diethylenetriaminepentaacetic acid (DTPA) reach concentrations of ca. $(2-2.5) \times 10^{-2}$ mol/L at 25 °C.

5.3.2. Separation Process

The ion exchange resin is initially loaded with NH_4^+. A solution of the salts of the rare earth elements to be separated is then passed through the column. The cations are absorbed by ion exchange onto the upper part of the column. The column is developed with a solution of the chelating agent, e.g., the triammonium salt of ethylenediaminetetraacetic acid.

In partition elution, the rare earth elements that form the most stable chelates are eluted first. The zones of the various rare earth elements are clearly separated from one other, but the eluted solutions are very dilute. This process is therefore used only for analytical purposes.

In displacement elution, a preliminary charge of a foreign ion (the so-called retarding ion) precedes the band of rare earth elements. This ion (denoted by R^{Y+}) has a lower affinity for the exchange resin than the rare earth elements. Displacement is now carried out using an ion that has a greater affinity for the resin than the rare earth elements. In some circumstances this ion can be NH_4^+. The sequence of affinities for the resin is then given by $NH_4^+ > RE_B > RE_A > R^{Y+}$. NH_4^+ displaces the RE_B ions almost quantitatively, while the RE_A ions displace the R^{Y+} ions. A band of constant length containing the rare earth elements moves through the column, and the concentration of the rare earth elements in the band remains constant. Between the zone containing pure RE_A and the zone containing pure RE_B there is a narrow zone containing both RE_A and RE_B.

By this method, more highly concentrated solutions of separated rare earth elements can be obtained than with partition elution. The same amount of resin can therefore be used to produce considerably larger quanities of rare earth elements.

The theory of displacement elution is described in [53]. Spedding and coworkers [54] have shown that, if the separation factor F_L is large enough, the band requires only a minimum movement ϑ along the column to achieve a constant equilibrium state. This relationship can be described as follows:

$$\vartheta = \frac{1 + (F_L + 1)\, x_i}{(F_L - 1)}$$

where x_i denotes the mole fraction of the rare earth element in the original mixture that has the lowest affinity for the resin and, therefore, the greatest chelating ability. If $x_i = 0.5$ (equimolar mixture of two rare earth elements) and $F_L = 2$,

the band must be moved along the column only 1.5 times its length to achieve equilibrium.

The cations in the equilibrium follow a logarithmic law. The molar fraction x_A of rare earth element A is a function of the number of theoretical plates n required to establish equilibrium:

$$x_A = \frac{F_L^{2n}}{1+F_L^{2n}}$$

A refinement of the ion exchange model is given in [55,56]. However, the equations given above are generally adequate for calculating the separation of the rare earth elements.

The main difficulty is the extrapolation from laboratory investigations to the industrial scale. The height equivalent to a theoretical plate (HETP) often becomes much greater (see Section 5.3.4).

Selection of Retarding Ions. The chelating ability of the weak aminopolycarboxylic acids increases with increasing pH. The H^+ ions can function as retarding ions:

$$REL^- + \overline{4H^+} \rightleftharpoons H_4L + \overline{RE^{3+}}$$

where REL^- denotes the dissolved ionic chelate of the rare earth metal. Owing to their low solubility, the acids tend to crystallize in the column. Only DTPA and HEDTA are sufficiently soluble at normal temperatures to enable H^+ to be used as the retarding ion for the separation of rare earth elements. EDTA can be used at 95 °C [57].

Many cations, e.g., Fe^{3+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, and Pb^{2+} have been investigated as possible retarding ions [58]. Of these, Cu^{2+} has been most widely used.

5.3.3. Industrial Processes

Ion exchange was first used for separating rare earth elements on an industrial scale in the late 1950s. However, it was largely replaced by liquid–liquid extraction during the 1960s, and only used if no suitable liquid–liquid extraction process was known. An example was the production of yttrium oxide [59–62], which, with europium oxide, is important as a red phosphor for TV tubes. However, yttrium oxide is now produced more economically by liquid–liquid extraction (see 5.4.3.2).

Since 1970, small amounts of rare earth elements have continued to be separated by ion exchange [e.g., those required in high purity (> 99.9999 %) for some electronic applications] or for the production of rare earth compounds with a very small market and which are only occasionally needed. A new phenol-based ion exchange resin was introduced by Unitika Ltd. of Osaka in 1989. The resin reportedly separates the elements to a purity approaching 99.999999 % and at a faster rate than previous resins.

DTPA and HEDTA have proved to be the most suitable chelating agents for the production of high-purity rare earth compounds [63]. One process for producing small amounts of very pure rare earth compounds makes use of the temperature effect, which not only enables much more concentrated solutions of chelating agents to be used, but also enables the separation factor to be modified [64,65].

New advances in continuous displacement chromatography (CDC) are mentioned in Section 5.3.

5.3.4. Disadvantages of Ion Exchange

Chelating agents are expensive and must be recovered after use, but recovery is difficult and requires a large number of batch operations. Al-so, the low solubility leads to very dilute solutions of the rare earth elements (2–10 g REO/L), whereas with liquid–liquid extraction 10–50 times more concentrated solutions may be used. These high dilutions lead to bulky equipment and handling losses.

On the laboratory scale, theoretical plate heights of the order of millimeters are often possible. On conversion to the industrial scale, the HETP increases considerably, and can reach 10–20 cm in columns 230 cm high and 63 cm in diameter.

For reasons as yet unexplained, the purifying effect decreases with increasing purity. This effect is less significant if rare earth elements are required with impurity contents of ca. 50 ppm, but it makes it almost impossible to reduce the impurity content to, e.g., 5 ppm.

5.4. Separation by Liquid – Liquid Extraction

5.4.1. Theoretical Basis

The liquid – liquid extraction process for the separation of the rare earth elements was discovered by FISCHER et al. who showed that extraction of rare earth metal solutions in hydrochloric acid with an alcohol, ether, or ketone gives separation factors of up to 1.5 [66]. The principles of this separation technique are described in →6. Liquid – Liquid Extraction and [1, part B 2], [67, 68].

In the liquid – liquid extraction process used today, the organic phase usually consists of two or more substances. The active extractant has chelating properties and is mainly responsible for the transfer of the dissolved rare earth elements from the aqueous to the organic phase. In some cases, active extractants can be used neat, but they are usually highly viscous or even solid and must be dissolved in a solvent to ensure good contact between the two phases. Suitable solvents are kerosene and aromatics. Usually, a modifying agent is added to the organic phase to improve the hydrodynamics and sometimes also alter the separation factor.

Distribution Coefficient and Separation Factor. The distribution coefficient is the fundamental parameter in liquid – liquid extraction. It is strongly dependent on concentration and is given by;

$$k = \frac{[\mathrm{RE}]_{\mathrm{organic\,phase}}}{[\mathrm{RE}]_{\mathrm{aqueous\,phase}}} = \frac{\overline{[\mathrm{RE}]}}{[\mathrm{RE}]}$$

The separation factor for two rare earth elements $\mathrm{RE_A}$ and $\mathrm{RE_B}$ is thus

$$\alpha_{\mathrm{REB/RE_A}} = \frac{k_\mathrm{B}}{k_\mathrm{A}} \frac{\overline{[\mathrm{RE_B}]}\,[\mathrm{RE_A}]}{[\mathrm{RE_B}]\,\overline{[\mathrm{RE_A}]}}$$

Method of Operation. (The technology of liquid – liquid extraction is described in →6. Liquid – Liquid Extraction).

The flow diagram of a countercurrent extraction plant for the continuous separation of two rare earth elements or two groups of rare earth elements is shown in Figure 8 [69]. The mixture of rare earths that is to be separated is fed into an intermediate stage of the liquid – liquid extraction plant operating in countercurrent flow. The extraction medium becomes preferentially charged with the rare earth metals (extract) that form the more stable chelates, while the less stable rare earth chelates remain preferentially in the aqueous phase (raffinate).

Figure 8. Principle of countercurrent liquid – liquid extraction

Figure 9. Mole fraction $\mathrm{RE_B}$ in the aqueous phase

This phase flows countercurrent to the extract, leading to further separation and preferential concentration of the more stable rare earth chelates in the extract (selective wash-out). The

rare earth metals are re-extracted for further treatment and the extraction medium is treated for re-use. At both ends of the plant, partial recycle takes place. If the recycle was total, separation into individual rare earth elements would take place, but this method is not practical, as it can only be operated batchwise, and a very long time is necessary for the establishment of equilibrium. The separation effect can be calculated by the McCabe – Thiele method in simple cases (Fig. 9).

5.4.2. Extractants

5.4.2.1. Neutral Extractants

The most effective extractant tri-*n*-butyl phosphate (TBP), with which the nitrates of the rare earths are usually extracted by the following generalized process:

$$RE(NO_3)_3 \cdot xH_2O + \overline{3\,TBP} \rightleftharpoons \overline{RE(NO_3)_3 \cdot 3\,TBP} + xH_2O$$

Separation factors between various rare earths and between the rare earths and yttrium are listed in Table 10 [70].

Concentrated nitric acid improves the selectivity. However, the strong acid solutions are difficult to handle, and the solubility of the rare earth nitrates in these is low. Furthermore, hydrolysis of the solvent takes place. A similar effect to that obtained with nitric acid can be achieved by adding nitrates that are not extracted by TBP, such as $Al(NO_3)_3$, alkali metal nitrates, or alkaline earth nitrates.

Pure TBP can be loaded with rare earth nitrates up to concentrations of 0.5 mol/L, corresponding to ca. 170 – 190 g REO/L. Temperature has a relatively small effect. The early development of mathematical models is described in [71]. A review of the many extraction processes with TBP is given in [72, 73]. Other salts of rare earth elements, e.g., perchlorates, chlorides, and thiocyanates have poor distribution coefficients or the selectivities are inadequate. The effect of low temperatures is described in [74].

Sulfoxides, RR′SO, behave analogously to TBP (Fig. 10), [75]. Alcohols and ethers, which were used in the early days, are no longer of importance.

5.4.2.2. Acidic Extractants

Organophosphoric acids are the second most important extraction media after TBP. They react with the rare earth elements in what is considered to be a cation-exchange extraction process, e.g., as follows:

$$RE^{3+} + \overline{3\,HL} \rightleftharpoons \overline{REL_3} + 3\,H^+$$

The most fully investigated and most readily available is di(2-ethylhexyl)phosphoric acid (DEHPA). In the hydrocarbons that are used as diluents, the acid is dimeric. In the case of the rare earth elements, it has been found that the exchange reaction depends on the diluent [76]. In aromatic diluents, the reaction is

$$RE^{3+} + \overline{3\,H_2L_2} \rightleftharpoons \overline{RE(HL_2)_3} + 3\,H^+$$

In aliphatic diluents it is

$$RE^{3+} + \overline{2.5\,H_2L_2} \rightleftharpoons \overline{REL(HL_2)_2} + 3\,H^+$$

The dimeric phosphoric acid is represented by H_2L_2. The distribution coefficient depends on the diluent, decreasing in the following order: kerosene > cyclohexane > CCl_4 > xylene > benzene. In accordance with the above equations, it is strongly affected by the strength, being inversely proportional to the third power of the concentration of H^+ ions for low concentrations of the rare earth elements. This effect, which is very important in nitric or hydrochloric acid solution, leads to a minimum value of the distribution coefficient at an acid concentration of 5 – 6 N [77].

The distribution coefficient increases with increasing atomic number of the rare earth element. Yttrium comes between Ho and Er, in accordance with its ionic radius. DEHPA is a very selective extraction medium, with a separation factor of ca. 2.4 for neighboring elements. The α values in $HClO_4$medium are listed in Table 11, [79].

Figure 11 shows the distribution coefficients as a function of atomic number. The high selectivity of DEHPA is clearly shown. Also, the "tetrad effect" can be seen, shown by a discontinuity after every fourth element. This effect also occurs in other properties of the rare earth elements and is associated with their electronic structure.

The influence of the anions of the rare earth salts on the separation effect is fairly small, although it does play a role in some cases. Thus, for example, chlorides or sulfates are suitable for the separation of Nd and Sm. Sulfates also appear to be somewhat more selective for the sepa-ration of the cerium earths from the other rare earth metals.

In general, the total concentration of the rare earth elements and the relative concentrations of the various elements do not greatly affect the separation factor.

Table 11. Separation factors in the system DEHPA/perchloric acid [78]

Cerium	Praseodymium	Neodymium	Promethium	Samarium	Europium	Gadolinium	Terbium	Dysprosium	Holmium	Yttrium	Erbium	Thulium	Ytterbium	Lutetium

					1.90	2.72	1.34×10^1	2.82×10^1	5.47×10^1	9.02×10^1	1.23×10^2	3.07×10^2	9.46×10^2	1.76×10^3	Samarium
						1.43	7.04	1.48×10^1	2.88×10^1	4.74×10^1	6.48×10^1	1.61×10^2	4.98×10^2	9.28×10^2	Europium
							4.93	1.04×10^1	2.01×10^1	3.32×10^1	4.53×10^1	1.13×10^2	3.48×10^2	6.49×10^2	Gadolinium
								2.11	4.08	6.73	9.21	2.29×10^1	7.06×10^1	1.32×10^2	Terbium
									1.94	3.20	4.37	1.09×10^1	3.35×10^1	6.25×10^1	Dysprosium
										1.65	2.25	5.61	1.73×10^1	3.22×10^1	Holmium
											1.37	3.40	1.05×10^1	1.96×10^1	Yttrium
												2.49	7.67	1.43×10^1	Erbium
													3.09	5.75	Thulium
														1.86	Ytterbium

Increasing the temperature tends to decrease the distribution coefficients and increases slightly the selectivity for the cerium earths, while that for the yttrium earths decreases.

Computer models for separation are described in [79,80]. Cerium(IV) is much more easily extracted than is the trivalent ion, and this effect has been utilized in the separation of cerium from fission products [81]. On the other hand, Eu^{2+} is much more difficult to extract than the RE^{3+} cations, so that an effective separation can be carried out from chloride solutions using HDEHP. However, ensuring that the europium remains in the divalent state during the extraction process is a problem [82].

Thermodynamic models for the prediction of distribution coefficients have been developed. In particular, a model has been presented for the extraction mechanism and chloride complexation when Sm, Eu, Gd, Tb, Dy, and Ho are extracted from acidic chloride solutions by DEHPA and 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester in kerosene [83].

Other Phosphorus-Containing Extractants. A large number of phosphorus compounds have been investigated [84]. Di-*n*-octyl-, di-*n*-butyl-, and di(octylphenyl)phosphoric acids are much more powerful extractants than DEHPA, but much less selective. Substituted phosphonic acids of the type (RO)R′PO(OH) are less effective than the corresponding phosphoric acids, and the substituted phosphinic acids of the type (R)(R′)PO(OH) are even less so. The general reaction is of the form

$$RE^{3+} + \overline{3\,H_2A_2} \rightleftharpoons \overline{RE(HA_2)_3} + 3\,H^+$$

Monoalkylphosphoric acids of the type $(RO)PO(OH)_2$, such as 2-ethylhexylphosphoric acid, have very low selectivity and fairly high solubility in the aqueous phase.

Very generally, the extraction ability of the organophosphoric acids decreases if the degree

of branching of the groups R or RO increases, if an RO group is replaced by the corresponding R group, or if OH is replaced by an R or RO group [85].

Carboxylic acids ($C_7 - C_{15}$) are soluble in hydrocarbons, and can be used as extraction agents. The extraction according to

$$\overline{3\,R_3CCOOH} + RE^{3+} \rightleftharpoons \overline{(R_3CCOO)_3RE} + 3\,H^+$$

is carried out in neutral or weakly acidic medium. The extraction properties of naphthenic acids are described in [86].

The most widely used acids are the Versatic acids (Shell) $R^1R^2(CH_3)C\text{-}COOH$, in which R^1 and R^2 are branched-chain alkyl groups. The most commonly used products are Versatic 911 with 9 – 11 C atoms and Versatic 10 with 10 C atoms.

In contrast to systems using TBA and DEHPA, which favour the extraction of nitrate and chloride, respectively, Versatic acid exhibits similar extraction behaviour for both chloride and nitrate anion. Heavy rare earths are also strongly extracted by this reagent. Separation factors for Versatic 911 are listed in Table 12 [70].

Investigations with complex-forming aminopolycarboxylic acids such as EDTA or DTPA are reported in [87].

5.4.2.3. Amines and Quaternary Ammonium Salts as Extractants

Long-chain amines will extract a large number of metall ions in the form of anionic complexes [88, 89].

Primary and secondary amines are relatively weak extractants for rare earth elements, so that high concentrations of salts or acids are necessary to achieve a useful separation effect. They preferentially extract rare earth sulfates. The poor selectivity can be considerably improved by the presence of EDTA and DTPA. In all cases, results are strongly dependent on pH and concentration, which can lead to problems in process control.

Tertiary amines are poor extractants. On the other hand, long-chain quaternary ammonium salts containing the cation $R^1R^2R^3(CH_3)N^+$ in which R^1, R^2, and R^3 represent $C_8 - C_{12}$ groups are effective, especially in the form of nitrates or thiocyanates [90, 91]. The rare earth elements are extracted from nitric acid solution and form hydrate complexes of the type$(R_4N)_2RE(NO_3)_5 \cdot x\,H_2O$. If a certain concentration in the organic phase is exceeded (ca. 35 g REO/L), separation of the complex from the diluent takes place due to its poor solubility. This phenomenon can be prevented by adding a modifying agent (e.g., a higher alcohol).

The distribution coefficients and selectivity depend on the anion (Fig. 12) [92]. In nitrate solutions, the light elements are more effectively extracted, but xttrium accompanies Tm. In thiocyanate solutions, complex formation in the aqueous phase plays an important role. The degree of extraction increases with atomic number, yttrium occupying a position between Nd and Sm [92]. Separation using quaternary ammonium salts in the presence of chelating agents such as oxalic acid, EDTA, DTPA, and HEDTA is described in [93, 94].

Figure 12. Distribution coefficients k_{RE} (relative to $k_y = 1$) for systems containing quaternary ammonium salts

Table 12. Separation factors between rare earths in the Versatic 911/Shellsol A system (nitrate or chloride) [70]

Adjacent	Ce/La	Pr/Ce	Nd/Pr	Sm/Nd	Gd/Sm	Dy/Gd	Ho/Dy	Er/Ho	Yb/Er	
elements	3.00	1.60	1.32	2.20	1.96	1.94	1.17	1.28	1.49	
Versus	La/Y	Ce/Y	Pr/Y	Nd/Y	Sm/Y	Gd/Y	Dy/Y	Ho/Y	Yb/Y	Er/Y
yttrium	0.028	0.085	0.14	0.18	0.39	0.77	1.50	1.75	2.25	3.35

5.4.2.4. Synergistic Effects

If a mixture of extractants is used, the distribution coefficient can be considerably greater than the sum of the coefficients of the individual extraction agents, although the opposite effect is also known. Several systems have been described but have not achieved industrial importance [95].

5.4.3. Industrial Liquid – Liquid Extraction

The first step is the selection of the extractant and the aqueous phase. An important cost question is the consumption of reactive chemicals, and depends on the nature of the extraction medium. When the rare earth salts are extracted by neutral extraction media or anionic complexes, only water is required. Separation using cationic complexes, however, requires a base for removal from the aqueous phase, and an acid for selective washing and re-extraction from the organic phase. Cationic extraction is therefore considerably more costly than anionic or molecular extraction, and is only used where its high selectivity is of major advantage (e.g., if a product of very high purity is required).

When choosing the extraction medium, the only decisive factor is selectivity, although a less selective solvent may be better if it has higher dissolving capacity. The number of extraction systems is so great that the difficulty does not usually lie in finding an effective system, but in finding a system that offers the best compromise between a number of criteria. Thus, each separation problem has its own particular solution.

In industry, the preferred extraction apparatus is the mixer – settler. The first step in liquid – liquid extraction can be either the separation of the rare earth elements from other elements or the concentration of the rare earth elements. In the first case, a solvent is chosen whose distribution coefficient for the rare earth elements as a group is markedly different from that of the other elements. In the second case, a solvent is required with high extraction ability for the rare earth elements, enabling it to extract them from dilute, and often acidic solutions. DEHPA is very suitable for this. A practical example is the process of Denison Mines, Elliot Lake (Ontario), in which a concentrate with ca. 60 % REO, very rich in yttrium (Y_2O_3/REO = 1 : 1), is produced from solutions containing 150 mg Y_2O_3/L acidified with sulfuric acid, from which the uranium has first been removed (Fig. 13) [96].

The next task is the separation of the rare earth metals from each other. A sequence of separation stages is established such that the required products are obtained. The process of separation depends as much on this as on the great diversity of starting materials.

Rhône-Poulenc can produce all the rare earth elements in a purity of > 99.999 % almost entirely by solvent extraction, except for a few elements for which this process is very expensive, and which are still produced in kilogram quantities by ion exchange. The principle of the separation is shown in Figure 14.

The mineral is first digested with NaOH, and two solutions–one of rare earth chlorides and another of rare earth nitrates–are produced. The next step in both cases is the removal of other, unwanted elements. The cerium earths and yttrium earths (to the Nd/Sm level) are then separated from each other. Purification is then carried out using all the types of extraction agents described above (amines, carboxylic acids, acidic and neutral organophosphorus compounds). The choice of the extraction agent depends not only on the separation factor, but also on economic considerations. Rhône-Poulenc operates with more than 1000 separation units, some difficult separations alone requiring 60 such units. The byproducts from the intermediate fractions are usually stored or separated by ion exchangers.

Figure 13. Denison Mines process for yttrium-rich rare earth concentrates [96]

The production capacity of Rhône-Poulenc is ca. 8000 t/a REO. Other companies producing rare earth compounds have mainly specialized in yttrium and europium, from which the red luminophors for television tubes are produced.

The Yao Lung Chemical Plant in Shanghai came on stream in 1964 and operates a similar process for cracking monazite as Rhône-Poulenc. The simplified flow sheet is described in [97]. Little is known of the Batou process for the beneficiation of the Baiyunebo ore in Inner Mongolia. The ore is principally mined for iron. A simplified flow sheet and principle of rare earth extraction and separation are described in [98].

5.4.3.1. Separation of Europium Oxide

The main problem in separating europium is its low content in the ores compared with the other rare earth metals. The classical minerals such as bastnaesite contain only 0.12 % Eu_2O_3 based on total REO content. Therefore a strongly enriched solution must first be prepared, from which the europium can be precipitated as its sulfate after first converting it to the divalent state.

The process used by Molycorp, Inc. is shown in Figure 15 [99]. The extraction consists of two consecutive cycles with several separation units operating with DEHPA. These concentrate the europium by a factor of 100 before it is precipitated.

5.4.3.2. Separation of Yttrium Oxide

The separation of yttrium oxide exploits the fact that yttrium is unique among the rare earth elements in that its position in the series of elements

Figure 14. Rhône-Poulenc liquid – liquid extraction process for separation of the rare earth elements

with respect to separation operations is not constant. The company As Megon has developed a process for producing high-purity yttrium starting from a xenotime concentrate [100]. The three extraction cycles are shown in Figure 16.

The first cycle consists of a selective extraction by DEHPA, followed by three re-extraction units. Four fractions are obtained, in one of which the yttrium is concentrated to 75 %.

The second cycle uses the nitrate of tricaprylmethylamine as extractant. The yttrium accompanies Tm, while the cerium earths are extracted. A Y – Tm – Yb – Lu mixture containing 95 % Y is obtained.

Figure 15. Molycorp process for the production of europium oxide [99]

The last cycle extracts Tm, Yb, and Lu by means of tricaprylmethylammonium thio-cyanate. Here, yttrium behaves like a cerium earth element. The only impurities in the yttrium oxide end product that exceed 1 ppm are Yb (2.5 ppm) and Er (3 ppm). From this product, 99.9999 % Y_2O_3 is obtained.

Molycorp starts from a concentrate containing 52 % Y_2O_3 in the REO mixture, and produces yttrium in two consecutive cycles

Figure 16. AS Megon process for high-purity yttrium oxide [100]

(Fig. 17), [101]. La – Er/Y – Lu are separated by Aliquat – NO_3^- with recycle, using the displacement effect of magnesium nitrate. Final purification of the yttrium is carried out with a Versatic acid, including a double recycle.

Thorium Ltd. developed the technique of total recycle in two consecutive systems. The first, 25-stage process operated with Versatic acid, and the second, 50-stage process with TBP. The product was 99.999 % Y_2O_3, starting from a

Figure 17. Molycorp process for production of pure yttrium oxide [101]

47 % concentrate [70, 75]. Details of other separation processes operated at one time by Thorium Ltd. have been published in [70].

5.4.3.3. Separation of Scandium

Scandium is present in all rare earth minerals, although only in trace amounts. Because it has similar chemical properties to the other rare earth elements, it cannot easily be obtained by selective precipitation as the oxalate or a double salt. The most effective separation is by extraction, scandium behaving quite differently from the other rare earth metals. For example, it is very readily extracted by diethyl ether from thiocyanate solution. TBP is an effective extractant from chloride solutions, while the other rare earth elements are hardly extracted. Organophosphoric acids such as DEHPA are much more effective extractants for scandium than for the other rare earth elements.

6. Production of the Metals

The electropositive character of the rare earth elements prevents their deposition from aqueous solution. Neither electrolytic processes in aqueous or organic media nor amalgam formation have never been very successful. However, they have achieved some importance for the production of high-purity compounds of samarium, europium, and ytterbium [102].

The rare earth metals are produced, both on the laboratory and industrial scale, by molten salt electrolysis and metallothermic reduction [1, part B 2], [2, vol 1, chap. 2, 173 – 232], [5, 6, 103].

6.1. Fused Salt Electrolysis

La, Ce, Pr, Nd, and the mixture of Nd and Pr known as didymium can be produced, like cerium mischmetal, by molten salt electrolysis of a mixture of anhydrous rare earth chlorides and fluorides with alkali and alkaline earth chlorides and fluorides [104] (see → Cerium, Cerium Alloys, and Cerium Mischmetal, Chap. 2.2.).

This process is made possible by the lower melting points of the cerium earth metals, whereas the yttrium earth metals have higher melting points and therefore do not melt during the electrolysis process.

A lower melting point can be achieved by using a cathode (e.g., Cd, Zn) that forms a low-melting alloy with the rare earth metal. This alloy can also have a lower density than the fused salt (e.g., Mg), so that it rises to the surface and can be removed from the fused salt [105]. The alloying element can then be removed by distillation.

By using molten Cd or Zn as cathode, Sm, Eu, and Yb can also be produced. Under the conditions used for cerium mischmetal, these elements are only reduced to the divalent state.

The production of rare earth metals and their alloys with 3*d* metals by molten salt electrolysis of the oxides dissolved in a fluoride melt has been described. The cerium earth metals are particularly suitable due to their low melting points [106].

The reactivity of the rare earth metals causes problems in the choice of construction materials of the electrolysis furnace. High-purity metals can be produced by using molybdenum, tungsten, or tantalum as the crucible and cathode materials. For industrial manufacture, iron crucibles with ceramic or graphite linings are used. If halogens are liberated during the electrolysis, carbon is used as the anode material. Molybdenum is also used in the electrolytic decomposition of the oxides in a fluoride melt.

6.2. Metallothermic Reduction

Metallothermic reduction of the rare earth oxides and anhydrous rare earth chlorides and fluorides can be used to produce high-purity rare earth metals, especially Gd to Lu, including Y. Metallothermic reduction is also used to produce rare earth mixtures with precisely controlled compositions that cannot be obtained by molten salt electrolysis. Alloys can also be produced by this process.

Alkali metals, alkaline earth metals, and aluminum are suitable reducing agents, as are alloys of these elements with each other. Lithium, which forms low-melting LiF, is of special importance, as is calcium. The use of Mg or Zn has the additional advantage of producing a low-melting alloy with the rare earth metal. The alloying elements can be removed by distillation, yielding the pure rare earth metal.

For the production of La, Ce, Pr, and Nd, the metallothermic reduction of the anhydrous rare earth chlorides is preferred. The reaction is carried out in crucibles lined with MgO at temperatures up to 1100 °C. At higher temperatures, reaction takes place between the rare earth metal and the MgO, and the rare earth chlorides vaporize. The process is not suitable for the production of Sm, Eu and Yb, which are merely reduced to the divalent state.

Gd to Lu and Sc, which have higher melting points, are obtained by reduction of the fluorides with Ca at 1500 – 1600 °C. The reduction is carried out in tantalum crucibles under a protective gas or in vacuum. The reaction temperature can be reduced by adding a "booster" such as iodine, which gives a slag with good flow properties that separates cleanly from the metal. Praseodymium is produced by reduction of the fluoride with lithium.

The Carlson – Schmidt apparatus is shown in Figure 18 [107]. This was used between 1957 and 1959 to produce high-purity yttrium metal in 50 kg batches.

Figure 18. Reduction apparatus for the production of yttrium [107]
a) Sight glass; b) Vacuum connection and helium inlet; c) Charging tunnel; d) Charging shut-off mechanism; e) Steel reaction chamber; f) Titanium reaction crucible; g) Graphite insulation; h) Titanium or steel supporting crucible; i) Water cooling

Sm, Eu, and Yb can be produced by reduction of the oxides with La or the cheaper cerium mischmetal at 1000 – 1300 °C. The rare earth oxides and the reducing metal are used in the form of pellets, prepared from chippings or thin disks.

Sm, Eu, and Yb are volatile at the reaction temperature under vacuum ($< 10^{-4}$ bar), and can be distilled from the reaction space during the reaction and condensed on coolers. Thus, these metals can be separated from rare earth metals that are not volatile under these conditions and obtained in a pure state. Hence, the starting materials can consist of rare earth oxides in which Sm, Eu, and Yb have merely been concentrated. The principle of the reduction – distillation apparatus is illustrated in Figure 19 [108]. Further purification can be carried out by a second distillation.

Figure 19. Reduction – distillation apparatus for the production of samarium, europium, and ytterbium [108]
a) Furnace; b) Heating element; c) Stainless steel container; d) Water cooling; e) Vacuum; f) Baffle; g) RE metal; h) Molybdenum condenser; i) Heat shield; j) Molybdenum crucible; k) Pelletized reactants

The calciothermic reduction of the rare earth oxides can be carried out such that a metal powder with a defined grain size distribution is produced. In this way, it is possible to produce alloys of rare earth metals with 3*d* metals that can be used to manufacture permanent magnets.

Methods of producing such alloys include, e.g., the coreduction process carried out under vacuum at 1000 °C for 3 h [109]:

$$RE_2O_3 + n\,Co_3O_4 + (10 - 3n)Co + (4n + 3)Ca \rightarrow 2\,RECo_5 + (4n - 3)CaO$$

where ($n = 0 - 10/3$), or the reduction – diffusion process carried out at 850 – 1150 °C for 5 h [110]:

$$RE_2O_3 + 10\,Co + 3\,CaH_2 \rightarrow 2\,RECo_5 + 3\,CaO + 3\,H_2$$

The CaO formed can be removed without affecting the properties of the metal powder.

If C and Si are used as reducing agents, rare earth carbides or silicides are formed. Prealloys or inoculation alloys containing rare earth metals are produced by reducing rare earth oxide mixtures or rare earth ore concentrates with CaSi or FeSi in an electric arc furnace.

6.3. Purification

Production of the pure rare earth metals necessitates the removal of products of the reaction of the metals with the atmosphere, crucible materials, and coreactants. Suitable methods inlcude melting under a protective gas or in a vacuum.

The high-boiling rare earth metals can also be purified by distillation. Tungsten powder is added to bind interstitial impurities (mainly C, N, O) as involatile compounds. Table 13 lists the temperatures at which the rare earth metals have vapor pressures of 1.3×10^{-3} to 1.3×10^{-5} bar [111].

Table 13. Vapor pressure and distillation rate of the rare earth metals [111]

RE element	Temperature, °C 1.3×10^{-5} bar	1.3×10^{-3} bar	Distillation rate at 1.3×10^{-3} bar, g cm^{-2} h^{-1}
Sc	1397	1773	33

Alloying elements and impurities such as Mg, Cd, Zn, and Ca are distilled off under vacuum. The remaining rare earth metal is then in the form of a sponge, which can be consolidated by fusion in an electric arc furnace.

Zone melting, melt extraction, and melt filtration, e.g., through tungsten powder, degassing in a high vacuum, etc., are other recommended purification methods.

7. Analysis

Analytical methods for the determination of the rare earth elements are reviewed in [5, pp. 570–593], [112]. Modern analytical methods are reported in [2, vol. 4], [113, 114].

Analysis may be divided into determination of individual rare earth elements, and group determination, in which the rare earth elements are coprecipitated as oxalates, hydroxides, or carbonates, and are then determined quantitatively after calcination to give the oxides. Complexometric titrations are also used for group analysis.

The ready conversion of cerium to the tetravalent state and of europium to the divalent state offer simple methods of titration for the single elements.

The determination of individual colored rare earth ions is normally carried out by spectrophotometry, emission spectroscopy, and spectroscopy in flames. Emission, absorption, or fluorescence methods are used. The technique and application of laser source mass spectrometry is discussed in [115].

X-ray fluorescence analysis can be used to determine concentrations in the range between 90 % and ppm quantities with moderate sensitivity. It is useful to concentrate the rare earth elements (sometimes with the aid of a trace collector), and to determine the individual rare earth metals in the separated oxide, since a direct determination on the matrix can lead to erroneous results due to the presence of foreign elements or to the physical or chemical condition of the sample. For the determination of yttrium, the K lines are preferably used, although the L lines are preferred for the other rare earths due to the disturbance of the K lines by bremsstrahlung spectra. Inner standards such as strontium or zirconium with yttrium are used, or standard samples that should be as similar as possible to the sample being tested. The spectra can then be used for quantitative determinations. The samples are prepared by compressing the material for analysis with borax.

8. Compounds

8.1. Hydrides [2, vol. 3, chap. 26, pp. 299–336]

All the rare earth metals react with molecular hydrogen to form the dihydrides, REH_2. Most rare earth metals will also react with hydrogen to produce the trihydrides, REH_3. The rate of reaction depends on temperature, hydrogen pressure, and the surface condition of the metal. Both forms of the hydride are nonstoichiometric, showing wide ranges of homogeneity. The dihydrides of La, Ce, Pr, and Nd have ranges of homogeneity with a composition approaching REH_3. The dihydrides of Sm, Gd to Tm, Lu, and Y have narrower ranges of existence and form a trihydride phase that is also nonstoichiometric. ScH_2, EuH_2, and YbH_2 are almost stoichiometric, but YbH_2 takes up additional hydrogen at very high pressures, up to the composition $YbH_{2.55}$. With the exception of EuH_2 and YbH_2, which form orthorhombic crystal structures similar to the alkaline earth hydrides, the dihydrides are cubic (fluorite structure). The trihydrides crystallize with a hexagonal structure.

Rare earth hydrides are brittle compounds, sometimes with a metallic luster. Similar to the transition metal hydrides, the rare earth dihydrides (except for YH_2 and EH_2) are metallic conductors. In particular, hydrogen-deficient dihydrides are better electronic conductors than their parent metals. In general, as the trihydride composition is approached the materials begin to show semiconducting properties.

Hydrides formed by the hydrogenation of binary rare earth solid solution alloys are usually considered to be solid solutions of the two parent rare earth hydrides, and as such their properties can be predicted with reasonable confidence from those of the constituent hydrides. In the case of binary alloys REM, where M is a non-rare- earth metal, the properties of the intermetallic hydride formed by hydrogenation of the alloy bear no relationship to those of the parent hydrides. They are therefore generally viewed as pseudobinary metal hydrides. Some of these materials can reversibly and efficiently absorb and desorb considerable amounts of hydrogen, and are therefore of commercial interest as a means

of storing hydrogen (see 8.1). A review of hydrogen absorption in intermetallic compounds is provided in [116].

8.2. Oxides, Hydroxides, Peroxides, Salts of Inorganic Oxoacids, Double Salts

Aspects of the transformation and defect structures in rare earth sesquioxides is provided in detail in [117]. The sesquioxides, RE_2O_3, of the rare earth elements, with the exception of Ce, Pr, and Tb, are obtained by oxidation of the metals with oxygen at elevated temperatures or by thermal or pyrohydrolytic decomposition of the hydroxides, halides, and certain oxosalts. In the case of Ce, Pr, and Tb, similar conditions yield the compounds CeO_2, Pr_6O_{11}, and Tb_4O_7, which can be reduced to the sesquioxides by hydrogen at elevated temperature. The sesquioxides melt at very high temperatures (in the range of 2200–2400 °C) and have very high enthalpies of formation [−1907.9 kJ/mol (Sc_2O_3) to −1661 kJ/mol (Eu_2O_3)].

They crystallize in the hexagonal system (type A), monoclinic system (type B) or cubic system (type C), depending on the temperature and the radius of the cation. At temperatures near the melting point, high-temperature modifications, types H and X, are also formed. Most sesquioxides are polymorphic, not including the two high-temperature forms. La_2O_3 forms type A crystals; Ce_2O_3 to Nd_2O_3 form types A and C; Sm_2O_3 to Ho_2O_3 form types C and B; and Er_2O_3 to Lu_2O, Y_2O_3, and Sc_2O_3 form only type C crystals. Whether the observed modifications are thermodynamically stable or metastable has so far been established in only a few cases.

Cubic crystals (fluorite type) are formed both by the dioxides of Ce, Pr, and Tb and by their intermediate oxides, in which cations in the two oxidation states 3+ and 4+ are present together. With the exception of CeO_2, which can be produced by air oxidation, the dioxides can only be obtained under strongly oxidizing conditions (e.g., oxygen at high pressure). The nonstoichiometric intermediate oxides have been extensively investigated in the system Pr–O [118]. Here, phases exist that are members of a series with the general composition Pr_nO_{2n-2} ($n = 7$, 9, 10, 11, 12).

The compound EuO is fairly easy to obtain by reduction of Eu_2O_3, e.g., with EuH_2 or Eu (g). With this exception, the condensed monoxides of the rare earth elements have only been observed as metastable compounds or as compounds stable under extreme conditions such as high pressure. For example, gaseous monoxides of all the rare earth elements have been observed at very high temperatures. EuO is a violet-black, cubic (NaCl type), ferromagnetic substance ($T_C = 70$ K). Eu also forms the oxide Eu_3O_4, in which both Eu^{2+} and Eu^{3+} ions are present.

The hydroxides, $RE(OH)_3$, are obtained as hydrates by the precipitation of RE^{3+} ions with ammonia or other bases. The hydroxides and oxide hydroxides, REOOH, can be prepared in crystalline form by hydrothermal synthesis. The hydroxides are sparingly soluble in water. Their basicity and solubility decrease with increasing atomic number. This progressive change in properties is important both for the separation of the rare earth elements from one other (see Section 5) and for chemical analysis. The hydroxides react with carbon dioxide to form basic carbonates, the rate of reaction depending on their basicity.

So far, very little is known of the existence of peroxides of the rare earth elements. Cerium peroxide forms as a deep brown, hydrated compound when Ce^{3+} ions are precipitated with ammonia and hydrogen peroxide. This intense colour can be used for the detection of Ce in the presence of other rare earth elements.

Of the group of compounds of rare earths with inorganic oxoacids, the carbonates, sulfates, nitrates, and certain double salts are of importance for analytical and preparative chemistry. Precipitation of RE^{3+} ions by solutions of alkali metal carbonates yields the sparingly soluble hydrated or basic carbonates. These are readily decomposed by acids or on heating, liberating CO_2. Apart from lanthanum sulfate, which forms a nonahydrate, the sulfates crystallize from aqueous solution as octahydrates. The hydrated sulfates can be thermally decomposed to the anhydrous form. They are fairly soluble, having a negative temperature coefficient of solubility, and are of industrial importance since sulfuric acid is used for digesting certain rare earth

ores. Double sulfates, e.g., salts of the type $RE_2(SO_4)_3 \cdot Na_2SO_4 \cdot n\,H_2O$ are important in the separation of the cerium earths from the yttrium earths.

The rare earth nitrates crystallize from solution in dilute nitric acid in the form of hydrates, $RE(NO_3)_3 \cdot n\,H_2O$ ($n \leq 6$). These salts are very soluble in water and moderately soluble in various organic solvents (alcohols, ketones, esters), and are important in the separation of the rare earth elements from each other by liquid – liquid extraction (see 5.4.2.1). Certain double nitrates, e.g., of the type $2\,RE(NO_3)_3 \cdot 3\,Mg(NO_3)_2 \cdot 24\,H_2O$ were at one time important in the separation of the rare earth elements by fractional crystallization. A comprehensive review of inorganic complex compounds is provided in [119, 120].

8.3. Halides

The rare earth elements, except for europium, form trihalides, REX_3, where X = F, Cl, Br, I. The trifluorides are sparingly soluble and are obtained from aqueous solution by precipitation with hydrogen fluoride. If these precipitates are dried at elevated temperatures, partial hydrolysis takes place, particularly of the more weakly basic elements. This can be effectively prevented by adding an excess of NH_4F or HF(g) during the dehydration process. With the exception of ScF_3, the trifluorides crystallize in the hexagonal LaF_3 structure ("tysonite structure") or the orthorhombic YF_3 structure, depending on the radius of the cation and the temperature range. ScF_3 crystallizes in the cubic system (REO_3 type). When dimorphism occurs, the YF_3 type is the low-temperature, and the LaF_3 type, the high-temperature modification. The trifluorides are high-melting compounds [1140 °C (HoF_3) to 1552 °C (ScF_3)]. EuF_3 and, to a very limited extent, YbF_3, tend to liberate fluorine at high temperatures. A review of the rare earth fluorides is given in [117].

The trichlorides can be obtained as their hexa- or heptahydrates by careful evaporation of their solutions in hydrochloric acid. The dehydration of the hydrates must be carried out in a stream of HCl and/or in the presence of an excess of NH_4Cl to prevent hydrolysis. On an industrial scale, the anhydrous trichlorides are obtained by reacting oxidic ores with chlorine and carbon (see 5.4.3). They crystallize in the hexagonal UCl_3 type structure ($LaCl_3$ to $GdCl_3$) or the monoclinic YCl_3 type structure ($DyCl_3$ to $LuCl_3$, YCl_3, $ScCl_3$). They are very soluble in water and in certain organic solvents such as ethanol and pyridine. Their melting points are in the range 588 ($TbCl_3$) to 892 °C ($LuCl_3$). With the exceptions of $EuCl_3$ and $YbCl_3$, which decompose on heating with liberation of chlorine, all the other rare earth chlorides vaporize without decomposition or sublime ($ScCl_3$).

The tribromides and triiodides are obtained in the same way as the trichlorides. The tribromides, and more so the triiodides of Eu, Yb, and Sm, have a marked tendency to lose halogen on heating, since the 2+ oxidation state of the cation becomes more stable with increasing size of the anion. The melting points of the tribromides are in the range 664 ($SmBr_3$) to 960 °C ($LuBr_3$), and those of the triiodides in the range 738 (PrI_3) to 1045 °C (LuI_3). The trihalides react with the sesquioxides to form oxide halides of various compositions.

The existence of tetrahalides is limited to the tetrafluorides of Ce, Pr, and Tb. CeF_4 and TbF_4 are obtained by the reaction of the elements or the trifluorides with fluorine. PrF_4 can only be obtained by the extractive removal of NaF from the readily prepared Na_2PrF_6 by treating it with liquid hydrogen fluoride in a fluorine atmosphere. The tetrafluorides are white solids which crystallize in the monoclinic system (UF_4 or ThF_4 type). They are slightly soluble in water but decompose to the trifluorides and are thermally unstable. Cerium tetrafluoride is appreciably more stable than the tetrafluorides of praseodymium and terbium.

The dihalides may be divided into two groups: the mainly salt-like compounds, in which the cation has a valency of 2+, and those compounds whose properties (e.g., electrical conductivity) indicate that the bond has some metallic character, and can be represented, in a much simplified way, by the general formula $Ln^{3+}(e^-)X_2$. Important methods of preparation include reduction of the trihalides by hydrogen at elevated temperatures (dichlorides, dibromides, and diiodides of Eu, Yb, and Sm, as well as EuF_2), or by solid or gaseous rare earth metals.

Thermodynamically stable difluorides are known only for Eu, Sm, and Yb. However, the

difluorides of almost all the other rare earth elements can be prepared as metastable compounds which crystallize in the cubic system (fluorite type). EuF_2, YbF_2, and SmF_2 can take up considerable quantities of the corresponding trifluorides in solid solution. Other dihalides of many rare earth elements can be prepared, but it is difficult to give definite trends for the occurrence of salt-like or metallic properties. However, it can be stated that all the dihalides of Sm, Eu, and Yb are of a mainly salt-like nature.

8.4. Chalcogenides

The rare earth elements form chalcogenides with the general formula REZ, RE_3Z_4, RE_2Z_3 (RE_5Z_7), and RE_2Z_4 (where Z = S or Se) [3, vol. 3, pp. 149 – 248], [121]. With Te, compounds are known with the formulae RETe, RE_3Te_4, RE_2Te_3, RE_4Te_7, $RETe_2$, RE_2Te_5, and $RETe_3$, of which some must be regarded as intermetallic compounds. The rare earth chalcogenides exhibit a wide range of structural, electrical, and magnetic properties. Most of them are very sensitive to hydrolysis and can therefore only be prepared and handled if moisture is excluded.

The monochalcogenides are mainly prepared by direct synthesis from the elements, but may also be prepared in some cases (YbS, YbSe, SmS, SmSe [20, 122]) by the reduction of higher chalcogenides with the corresponding gaseous rare earth metal. EuS and EuSe are also obtained by the reaction of Eu_2O_3 with H_2S/H_2 or H_2Se/H_2 at ca. 1100 °C. All the rare earth monochalcogenides crystallize in the cubic system (NaCl type) and have high melting and boiling points. Thus, for example, the compound CeS has been recommended as a sulfide ceramic material for coating vessels due to its inertness to many metals [123]. It begins to liquefy above 2100 °C, and melts at 2450 °C. Despite the 1 : 1 stoichiometry, only the monochalcogenides of Eu, Yb, and Sm can (within limits) be regarded as compounds of RE^{2+}. The other compounds have properties that show the simultaneous presence of ionic and metallic bonding.

The sesquichalcogenides, RE_2Z_3 (Z = S, Se, or Te), can also be prepared by direct synthesis from the elements (the only practical method for the tellurides), or by reaction of the sesquioxides or trihalides with the hydrogen chalcogenides at high temperatures. When the oxides are used, very stable oxide chalcogenides such as RE_2O_2Z can be produced as intermediate products. The sesquichalcogenides can exist in several modifications. The cubic modification is nonstoichiometric, with the approximate composition RE_3Z_4 (Th_3P_4 type).

Rare earth polychalcogenides include the polysulfides RE_2S_4. With the exceptions of the polysulfides of Tm and Lu, they are obtained by heating the sesquisulfides with an excess of sulfur. They are interesting in that they are not RE^{4+} compounds, but contain two S^{2-} ions and one S_2 group per formula unit.

The crystal chemistry and phase equilibria of rare earth ternary systems with chalcogen elements is dealt with in [124].

8.5. Nitrides

The rare earth elements react with nitrogen to give nitrides of the type REN [125], and with the elements P, As, Sb, and Bi to give compounds with other stoichiometric compositions. The nitrides are formed in slow reactions of nitrogen with the metals or hydrides in very finely divided form at ca. 1000 °C, or more readily by reaction with ammonia at ca. 700 °C. The nitrides are cubic (NaCl type) and have very high melting points and decomposition temperatures. They have a metallic appearance when in a compact form, and are ionic compounds with metallic conductivity or semiconductors. Apart from ScN, all the rare earth nitrides are very sensitive to hydrolysis, and can therefore only be handled when moisture is excluded.

8.6. Carbides

Of the rare earth compounds with elements of group 14, only the carbides are described here. Compounds with the formulae REC_2, RE_2C_3, RE_2C, and REC_{1-x} are known. Of these, the carbides REC_2 represent the largest group [3, vol. 3, pp. 284 – 342]. The carbides can be synthesized directly from the elements. The high-melting dicarbides are highly involatile, crystallize in the tetragonal system (CaC_2 type), and are metallic conductors with approximately one

conducting electron per C_2 group. Hydrolysis of the carbides under neutral or weakly acidic conditions leads to complex mixtures of unsaturated and saturated hydrocarbons, most of which are C_2 hydrocarbons due to the presence of C_2 groups in the crystal structure.

8.7. Complexes; Organic Compounds

From the point of view of complex-forming properties, the rare earth elements resemble the elements of group 2 more closely than those of the 3*d* transition elements, owing to the peculiarities described in Section 3.2.4. Only very strong ligands, with strong chelate-forming properties, are able to form thermodynamically stable, isolable rare earth complexes.

Many rare earth chelates are very difficult to isolate from aqueous solution, as water is an extremely strong ligand for rare earth ions. Also, ligand exchange reactions take place very rapidly in solution, which makes it impossible to isolate definite isomers. Of the rare earth chelate compounds so far prepared (e.g., [3, vol. 3, pp. 61 – 128], [126]), those useful for liquid – liquid extraction and separation of rare earth elements are of particular interest. The technically important chelating agents include certain ketones, but, above all, tri-*n*-butylphosphate (TBP) [3, vol. 1, pp. 89 – 109]. The chelates of the rare earth elements with 2,4-pentanedione (acetylacetone) and its derivatives are also important, these being characterized by great stability and sometimes considerable volatility [127].

When considering organic compounds [1, part D 1 – D 3], [128], a distinction should be made between true organometallic compounds and salts of organic acids or coordination compounds with organic ligands. The relatively small number of true organic compounds (e.g., the tris(cyclopentadienyl) derivatives [129] and the triphenylene and anionic tetraphenyl complexes [130, 131]) are mostly very reactive, sensitive substances. Of the large group of salts of organic acids, the oxalates deserve mention. These are formed as sparingly soluble precipitates from solutions in moderately concentrated hydrochloric acid and are important for the purification of the rare earth elements, and also for their quantitative determination. Organometallic compounds of the rare earth elements are discussed in [132].

9. Uses [3, vol. 1, pp. 416 – 500; vol. 2, pp. 190 – 297]

The rare earth metals and their compounds are used in numerous areas of industry for a wide range of purposes. The most important of these include metallurgy, catalysts in the chemical industry, coloring of glass and ceramics, the production of magnets, and phosphors.

Metallurgy. The importance of the rare earth metals in metallurgy is highlighted in [133, 134]. In 1990, ca. 22 % by volume of rare earth consumption in the United States was devoted to metallurgical end use. The equivalent volume usage in Japan by contrast was ca. 10 %. One of the most important areas of application, is based on their reactivity with water, hydrogen, nitrogen, sulfur, and the so-called tramp elements such as arsenic, antimony, and bismuth. Sulfur reacts to form rare earth sulfides or oxysulfides in spheroidal form which are not deformed under rolling conditions, and which form solid particles at the temperature of molten steel, thus improving the hot formability and flexibility of microalloyed steels, and reducing anisotropy in the notched toughness test. Rare earths are used in the form of mischmetal containing principally Ce, La, and Nd.

The addition of rare earth metals such as yttrium and cerium, or cerium mischmetal imparts improved oxidation resistance to heating element alloys, to substrate alloys for catalysts, and to superalloys. Rare earth metals improve the precipitation of spheroidal graphite in SG iron casting. Although for economic reasons cerium mischmetal is more often used in these applications than the pure rare earth metals, the pure metals can give better results when used separately.

Addition of rare earths to copper and aluminum alloys, used as electrical conductors, improves the mechanical properties. In China, an yttrium – magnesium – aluminum alloy has been developed for transmission cabling. Yttrium improves tensile strength, heat resistance, vibration resistance and can raise electrical conductivity by 50 %. Creep resistance and tensile strength

at high temperatures are improved by addition of rare earth metal (mainly neodymium, praesodymium, and yttrium) to magnesium alloys for pressure casting and aircraft construction. Significant improvements to high strength Al–Mg and Al–Li alloys are achieved by the addition of scandium. Similar effects can be achieved with titanium and titanium alloys, and with alloys of niobium, tantalum, and vanadium.

The rare earth metals react readily with gaseous elements, and are therefore used as getters. Their pyrophoric properties are utilized in friction igniters ("flints") (→ Cerium, Cerium Alloys, and Cerium Mischmetal) and in military projectiles.

Alloys of the type $LaNi_5$ are capable of absorbing hydrogen, even from mixtures with other gases, forming rare earth hydrides. These are used to store hydrogen reversibly. In these alloys La can be partially replaced by Ce, Pr, and Nd, and Ni by Co, Cr, Cu, Fe, or Mn. They can also be used to separate D_2 from H_2 [135–138].

Rare earth alloys with 3 d transition elements have magnetic properties, [2, vols. 14, 16], [139, 140]. These alloys are of the type REA_5 or RE_2A_{17}, in which the rare earth metals can be cerium earths, especially Sm, and the 3*d* transition metals can be pure Co, or Co partially replaced by Fe, Mn, Cr, or Cu. These alloys give extremely stable magnets, having energy products, high remanence, and high coercive field strengths [141–143] (see also →Magnetic Materials, Chap. 4.2.). Some typical properties are given in Table 14. These high-power magnets are used in small motors, printers, quartz watches, headphones, loudspeakers, magnetic storage, traveling-wave tubes, etc., mainly in miniaturized equipment.

Rare earth alloys also exhibit very large magnetostriction at cryogenic temperatures. $REFe_2$ Laves phase compounds show very large magnetostriction but possess intrinsic magnetocrystalline anisotropy [2, vol. 2, chap. 15, pp. 231–258]. For many applications, high strain is required at low magnetic fields, and therefore anisotropy must be minimized. The most important material to emerge from research activity so far is the ternary alloy $Tb_{0.27}Dy_{0.73}Fe_2$, which shows promise for high power actuators, transducers, and sensors.

Catalysts [117, vol. 5, chap. 43, 217–320]. A further important use for rare earth elements (as their chlorides or nitrates) is in zeolite cracker catalysts for the improvement of gasoline yields and reductions in the formation of coke and light hydrocarbons. These catalyst compositions can correspond either to the natural composition of the cerium earths or can be based mainly on cerium [144].

Rare earth elements are also used as catalysts for alkylation, isomerization, hydrogenation, dehydrogenation, dehydration, reforming of hydrocarbons, polymerization, oxidation of CO and hydrocarbons [145, 146], and reduction of the concentration of nitrogen oxides in automobile exhaust gases [147]. The formation of hydrides enables them to be used as methanation catalysts [148]. Cerium stabilizes γ-Al_2O_3 as a carrier for noble metal catalysts [149, 150]. Rare earth chelates with diketones can replace lead compounds as antiknock agents [151].

Energy Production. Rare earth elements have a possible future use in energy production. $RENi_5$ [152], La_2O_3, Y_2O_3, and CeO_2, with Ni, Co, Cr, or Zn [153], can be used as electrodes in fuel cells, while the solid electrolyte can be ZrO_2 stabilized with Y_2O_3, $ZrO_2-Y_2O_3-Ta_2O_5$, or $ZrO_2-CeO_2-Y_2O_3$ [154, 155].

Water, in the form of a photooxidizable compound with Eu^{2+}, is reduced in the first stage, and in the second stage the Eu^{3+} formed is reduced by a light-sensitive transition metal complex [156]. Water can be oxidized by Ce^{4+} in the presence of the redox catalyst PtO_2 or IrO_2, and the Ce^{3+} produced reconverted photochemically to Ce^{4+}, with liberation of H_2 [157]. The low Curie point (20 °C) of Gd can be utilized to produce a heat pump [158].

In magnetohydrodynamic generators, $LaCrO_3$ [159] and $LaCoO_3$ [160] are used as electrodes, and LaB_6 [161] as an electron emitter.

Glass and Ceramics. Another important use of rare earth elements is in the glass and ceramic industries [162]. Rare earth oxides in their naturally-occurring composition or with an increased CeO_2 content (or pure CeO_2) are used as polishing agents in the glass industry. Other uses of Ce include the chemical decolorization of glass ($Fe^{2+} \rightarrow Fe^{3+}$) [163], reduction of UV

Table 14. Characteristic properties of selected rare earth based permanent magnetic materials

Material	Energy product $(BH)_{max}$, kJ/m^3	Remanence B_r, mT	Coercivity before polarisation H_{cb}, kA/m	Coercivity after polarisation H_{cj}, kA/m
$SmCo_5$	160	920	2500	680
$(Sm_{0.4}Pr_{0.6})Co_5$	200	1050	1200	720
$(Sm_{0.2}M_{0.8})Co_5$	120	800	1000	580
$Sm(Co,Cu,Fe)_5$	110	770	300	290
$Sm(Co,Cu,Fe,Zr)_{6.9}$	240	1130	580	540
$Sm(Co,Cu,Fe,Zr)_{7.5}$	210	1080	800	780
NdFeB	300	1300	1000	700
NdDyFeB	250	1100	2000	880

transparency of glass containers for foodstuffs and medicines, and the prevention decolorization of television screens by X-rays and γ rays.

Nd (blue to wine red), Pr (green), Er (pink), and Ho (blue) can be used both for coloring glass and for color neutralization. Combinations of these with each other and with other elements such as Ti(+Ce: yellow), Se(+Nd: violet), and Ni(+Nd: reddish) give further effects.

In optical glasses for lenses, La improves the refractive index and dispersion. La and Gd also improve chemical and mechanical properties, and enable these types of glass to be used under the demanding conditions of magneto-optical and electro-optical systems [120, chap. 58, pp. 1–90].

In very pure types of glass, Eu^{2+} and Ce^{4+} give a phototropic effect in sunlight.

In the ceramic industry, rare earth oxides are used as yellow pigments (Pr) [164], as opacifiers in glazes and enamels (Ce) [165], for radiation-shielding ceramics (Sm, Eu, Gd, Dy) [166], to improve the light fastness of lead chromate and titanium dioxide pigments, to impart "natural" fluorescence to artificial teeth (Eu, Sm, Ce) [167–169], and especially as stabilizers for cubic ZrO_2 [170]. An interesting application is in so-called lambda probes, in which Y_2O_3-stabilized ZrO_2 is the solid electrolyte in a measurement/control system that optimizes oxidation and reduces the content of harmful gases in automobile exhausts [171]. In a similar application, it is used for determining the O_2 content of liquid steel [172].

CeS and Y_2O_3 can be used for the manufacture of crucibles and as temperature-resistant materials for gas turbines [173]. The mechanical properties of Si_3N_4 are improved by the addition of rare earths to promote sintering [174].

Electronics. Compounds of the type $Pb_{1-x}La_x(Zr_{1-y}Ti_y)O_3$ (PLZT) are used as electro-optical ceramics in displays [175], as electromechanical transducers [176], and for their piezoelectrical properties [177]. Lanthanum doped $BaTiO_3$ is used as a dielectric in capacitors [178], and in thermistors [179].

Compounds of the garnet type such as $Y_3Al_5O_{12}$ (YAG), $Y_3Fe_5O_{12}$ (YIG), and yttrium orthoaluminate $YAlO_3$ (YALO), doped with neodymium, are used as solid state lasers [2, vol. 4, pp. 275–315]. Solid state Nd–YAG lasers (→ Lasers, Chap. 3.3.), operating at 1064 nm wavelength, are most popular for cutting, welding and metal heat treatment. In Japan production is growing at ca. 10 %/a. Ho–YAG and Er–YAG lasers, emitting at 2000 nm and 2900 nm, respectively, have been developed to partly replace CO_2 lasers for use in microsurgery. In 1986 Sumitomo Metal Mining Company produced single crystals of gadolinium aluminum scandium garnet (GASG). These laser materials doped with nickel and chromium are expected to capture some of the tunable and high-power laser markets. $Y_3Fe_5O_{12}$ (YIG) is also used in frequency control applications [180, 181]. $Gd_3Ga_5O_{12}$ (GGG) crystal contains 53.7 % gadolinium oxide and is used for bubble type magnetic information storage [182] as well as in the doped form (ca. 3 atom %Nd) for high-power pulsed lasers. Rare earths used in laser technology are of very high purity (> 99.999 %) and therefore have high added value.

Rare earth–transition metal alloys deposited onto glass or polycarbonate provide an excellent magneto-optical medium for high density data storage and retrieval. Films are generally deposited by sputtering, and the targets used in

the process usually contain terbium, gadolinium, dysprosium, or neodymium together with cobalt and iron and other minor elements. Rare earth halides of Eu and Yb have semiconductor properties [183].

Phosphors [2, vol. 4, pp. 237 – 274] (→ Luminescent Materials). Stimulation by UV, X-rays, or electron beams causes certain rare earth elements to emit light of a definite wavelength. The energy is transferred from the host lattice to an activator. The following can act as host lattices: oxide sulfides and vanadates of Y, La, Gd, and Lu (favorable $4f$ electron configurations), and borates, aluminates, phosphates, silicates, tungstates, fluorides, compounds of the ruby type, etc. Phosphors containing rare earth oxides are used in color cathode ray tubes, X-ray intensifying screens, and fluorescent lamps. The following are used as red emitting phosphors in cathode ray tubes for TV and VDU screens: $YVO_4:Eu^{3+}$ (4.5. %), $Y_2O_3:Eu^{3+}$(3.5 %), and $Y_2O_2S:Eu^{3+}$ (3.65 %). Examples of green-emitting phosphors are $La_2O_2S:Tb^{3+}$, $CaS:Ce^{3+}$, and $SrGa_2S_4:Eu^{2+}$. Blue phosphors include $Sr_5Cl(PO_4)_3:Eu^{2+}$ and $ZnS:Tm^{3+}$. Other rare earth activators are Ce^{3+} (UV, blue), Pr^{3+} (red, green, blue, UV), Nd^{3+} (IR, lasers), Sm^{3+} (orange), Eu^{2+} (blue, green), Tb^{3+} (green), Dy (yellow, white), Er (green, lasers), Ho (green, yellow, lasers), Tm (blue), and Yb (green). Other areas of use include high-sensitivity X-ray films, optical scanning devices, photocopying equipment, and scintillation crystals [184]. Rare earth fluorides and oxides are still added to the carbon of classical carbon arc lamps, e.g., for cinemas, to improve light emission [185]. In 1991, 73 % by volume of the rare earths used in phosphors was associated with yttrium, 5 % with europium, 4 % with terbium, and 18 % with other rare earth elements.

Reactor Technology. Sm, Eu, Gd, and Dy have high thermal neutron capture cross sections. Eu and Dy can take up five neutrons in succession. Therefore, they have a low rate of burn off when used in control rods or in ceramics for radiation protection [166]. Table 15 lists the thermal neutron capture cross sections of these elements.

Other Applications. Rare earth compounds are used in the paint industry as dryers [186]. They are also used in the textile industry [187] and as oxidizing agents for self-cleaning ovens [188, 189].

Europium complexes are used as shift reagents in NMR spectroscopy [190].

Rare earth elements can be used in the third stage of wastewater purification for the precipitation of phosphates [191].

10. Economic Aspects [192]

World production of rare earth minerals totalled ca. 96 500 t (57 000 t REO) in 1990, compared with an estimated output of ca. 107 500 t (64 000 t REO) in 1989. The decrease in mineral output over these two years has been associated with a decrease in Australian and Chinese production. In particular, up to 1988 production and pricing policy of raw materials and separated rare earth elements were essentially stable. Chinese production and export of these products increased dramatically between 1988 and 1990 without a parallel increase in market demand, thus causing some destabilization of world pricing policies. Prices of rare earth materials during this period dropped by between 20 and 70 %, depending on the rare earth element. China's export revenues also suffered a 40 % decrease. Some stability has returned to the world market with China reducing output of rare earth minerals from 43 000 t (25 250 t REO) in 1989 to 27 500 t (16 500 t REO) in 1990, and to 16 000 t REO in 1992. Exports of raw materials also dropped by 50 % in 1990 and by 46 % in 1991.

World rare earth consumption grew by less than 3 % annually between 1980 and 1990 against a predicted growth of 6 %. In 1980 the demand for rare earths expressed as oxide (REO) was ca. 27 000 t. Rare earth consumption in 1990 is estimated at 35 000 t with a market value of ca. $\$400\times10^6$. Ores, concentrates and mixed rare earth compounds account for ca. 75 % of the tonnage consumption but only 25 % of the total market value.

Rare earths in the form of metals and separated high-purity oxide for use in applications such as phosphors, magnets and superconduc-

Table 15. Thermal neutron capture cross sections of some rare earth elements in n, γ reactions

Rare earth element	Number of absorbing isotopes	Relative atomic mass	Abundance in nature, wt %	Thermal neutron capture cross section, 10^{-28} m^2	
				For natural isotope mixture	For single isotopes
Sm	1	149	13.8	5 600	66 000
Eu	5	151	47.8	4 300	9 000
		152			5 000
		153	52.2		420
		154			1 500
		155			13 000
Gd	2	155	14.9	46 000	70 000
		157	15.7		180 000
Dy	5	160	2.3	950	130
		161	18.9		680
		162	25.5		240
		163	24.9		220
		164	28.2		2 780

tors, demand much higher added value and account for nearly 75 % of the market.

Estimates of world rare earth consumption by end use for 1990 and predicted values for 1996 are shown in Table 16. However, as is shown in Table 17, the balance of consumption for end use applications varies significantly between the major user countries. This can reflect differences in technological status, future commercial strategies, and the availability of rare earth stock.

New developments based on the less common rare earth elements or requiring only a single rare earth element can affect the supply/demand situation. A favorable cost/price situation will only exist if there is a good market for all the principal rare earth elements that occur in nature, since rates of production of the elements by the rare earth industry are interdependent.

Table 16. World markets for rare earth consumption by end use [192]

Use	1990		Predicted for 1996	
	% vol	% by value	% vol	% by value
Phosphors	3	37	4	40
Magnets	7	20	15	23
Catalyst	40	16	35	11
Glass	18	12	17	10
Metallurgy	26	4	22	2
Ceramics	2	6	2	8
Other	4	5	5	6
Total	100	100	100	100

Prices of rare earths can vary significantly depending upon the abundance of the rare earth element in the ore, the source of the product, the purity of the element or compound required, and the quantity of material purchased.

Approximate prices of rare earth oxides are given in Table 18. Reviews of the rare earth industry are given in [14, 192–194].

11. Toxicology

The pure rare earth metals and their compounds are regarded as having low toxicities with respect to the Hodge – Sterner classification system [195]. Haley describes the rare earth elements as only slightly toxic [2, vol. 4, pp. 553 – 585], [196]; see also [1, part B 2]. A further extensive review on this subject is provided by Arvela [197].

Several authors investigations into the inhalation of rare earth oxides by humans (smoke from carbon arc lamps in cinemas) have been carried out [198–200]. Chest X-rays show changes to the lungs caused by dust deposits, although these harmful effects are not caused by the rare earth elements, but by radioactive impurities, i.e., products of the radioactive decay of thorium and uranium. Modern methods of rare earth separation together with an increased use of bastnaesite have led to rare earth products that are virtually free from Th and U.

Experiments on animals showed that intravenous injection of rare earths caused impairment of liver function.

Table 17. Rare earth consumption by end use application [192]

Application	United States 1989		Japan 1990		China 1990	
	% vol	tonnes REO	% vol	tonnes REO	% vol	tonnes REO
Glass and ceramics	43	7 524	67	3 639		
Catalysis	42	7350			30	2200
Metallurgy	14	2 450	4	217	56.5	4100
Permanent magnets			18	978	3	216
Agriculture					6.5	480
Phosphors			5.5	299		
Other	1 ∗	175 ∗	5.5 ∗∗	299 ∗∗	4	260
Total	100	17 500	100	5432	100	7256

∗ Includes permanent magnets, phosphors, and electronics.
∗∗ Includes catalysis.

Table 18. Approximate prices of rare earth oxides in 1990 [192]

Rare earth oxide	Rhône-Poulenc		Molycorp	
	Purity, %	$/kg	Purity, %	$/kg
Cerium	99.50	25.75	99.0	19.25
Dysprosium	95.00	132.00	96.00	132.00
Erbium	96.00	190.00	98.00	143.00
Europium	99.99	1960.00	99.99	1639.00
Gadolinium	99.99	136.50	99.99	132.00
Holmium	99.90	510.00		
Lanthanum	99.99	23.00	99.99	19.25
Lutetium	99.99	7000.00		
Neodymium	95.00	20.00	99.90	88.00
Praseodymium	96.00	38.85	96.00	37.00
Samarium	96.00	175.00	96.00	143.00
Terbium	99.90	880.00	99.90	825.00
Thulium	99.90	3600.00		
Ytterbium	99.00	230.00		
Yttrium	99.99	115.50	99.99	115.50

1. Introduction

The most important distinguishing characteristic of reactive dyes is that they form covalent bonds with the substrate that is to be colored during the application process. Thus, the dye molecule contains specific functional groups that can undergo addition or substitution reactions with the $-OH$, $-SH$, and $-NH_2$ groups present in textile fibers.

Cross and Bevan first succeeded in fixing dyes covalently onto cellulose fibers (in 1895) [1], but their multistep process was too complicated for practical application. Early work by Schröter with sulfonyl chloride-based dyes was unsuccessful [2], but Günther later did succeed in fixing derivatives of isatoic anhydride onto cellulose fibers [3].

An alternative approach is to modify the fibers themselves and then introduce the coloration. For example, cellulose can be reacted with 4-nitrobenzyldimethylphenylammonium hydroxide or 3-nitrobenzyloxymethylpyridinium chloride, followed by reduction, diazotization, and coupling to a dye [4]. Another process, invented by Haller and Heckendorn, involves treating the cellulose with cyanuric chloride in an organic solvent and then reacting the product with an amino group-containing dye [5].

The first industrially important reactive dye systems were developed for wool, and took advantage of the chloroacetylamino [6] and the chloroethanesulfonyl groups [7]. Vinylsulfonyl- and 2-sulfooxyethanesulfonyl groups were found to be applicable to both wool and cellulose. Heyna and Schumacher patented some of the first dyes of this type in the 1940s [8, 9], and vinylsulfone dyes continue to be of great importance.

The dyes described in [8] entered the market for wool in 1952 under the trade name Remalan, followed a year later by the Cibalan dyes from Ciba-Geigy, which contained monochlorotriazinyl reactive groups [10]. In 1953 Rattee and Stephen were able to fix chlorotriazine-containing dyes onto cellulose in basic, aqueous solvents, representing an economic breakthrough for the reactive dye concept [11].

Introduction of the Procion-MX dyes by ICI in 1956 was followed in 1957 by the appearance of the Remazol dyes from Hoechst and the Cibacron dyes from Ciba-Geigy. The year 1960 brought the Levafix dyes from Bayer and the Drimaren range from Sandoz. Other significant developments included the introduction of multiple-anchor dyes (Solidazol, Cassella, 1975; Sumifix-Supra, Sumitomo, 1981), fluorotriazine-containing reactive dyes (Ciba-Geigy, 1978), and fluorotriazine-containing multiple-anchor dyes (Ciba-Geigy, 1988).

The development of reactive dyes has continued to be rapid, and world demand for such materials reached ca. 97 000 t in 1990, valued at ca. € 2×10^9 . Reactive dyes thus constitute the largest of the textile dye classes on a monetary basis, accounting for ca. 17 % of the textile dye market by volume.

2. Reactive Systems

Reactive dyes are often classified according to the number of reactive systems they contain, leading to the terms mono-, double-, and multiple-anchor dyes. On the world market, the first two categories are of greatest importance; multiple-anchor dyes (those with three or more reactive groups) play a more minor role and will be discussed here only briefly (Section 2.3).

2.1. Mono-Anchor Dyes

Most mono-anchor dyes are derivatives of cyanuric chloride (2,4,6-trichloro-1,3,5-triazine [*108-77-0*]), a molecule of wide synthetic potential because the three chlorine atoms on the triazine ring differ in their reactivities [12]. The first chlorine atom exchanges with nucleophiles in water at 0 – 5 °C, the second at 35 – 40 °C, and the third at 80 – 85 °C. A wide variety of triazinyl dyes can thus be prepared by careful selection of the reaction conditions. Condensation of cyanuric chloride with a chromophore ("Chrom.") containing an amino group yields the highly reactive dichlorotriazinyl dyes (e.g., Procion MX) [11]. These very reactive dyes are sensitive to hydrolysis, and a suitable buffer is usually added to the powdered dye to increase its stability [13].

Procion MX

When two of the chlorines are substituted, for example with amino or alkoxy groups, monochlorotriazinyl dyes such as Procion H, Procion P, and Cibacron are obtained. These are considerably less reactive, and thus react with cellulose in the exhaust dyeing process only at relatively high temperature (80 °C). Such dyes are especially advantageous for printing [14].

The reactivity of monochlorotriazinyl dyes can be increased by replacing the chlorine with fluorine, permitting the exhaust process to be carried out at 40 °C [15].

Cibacron F

Reaction of monochlorotriazinyl dyes with tertiary amines also yields highly reactive dyes, such as Kayacelon React and Procion H-EG. One advantage conferred by the ammonium groups in these dyes is high water solubility [16].

Kayacelon React/Procion H-EG

The reactivity of dyes of this type is strongly influenced by the choice of tertiary amine. Nicotinic acid is preferred because it acts as a good leaving group and introduces comparatively little odor into the dyeing bath. The ammonium residue is also a better leaving group than, for example, chlorine, permitting the exhaust process to be conducted at 40 – 60 °C. In contrast

to halogen-containing triazinyl dyes, these dyes do not require alkali in the application process, so dyeing can be conducted under neutral conditions.

In addition to the 1,3,5-triazines, other classes of heterocycles are important for the dyeing of cotton. Especially noteworthy are the halopyrimidine dyes distributed under the trade name Drimaren [17].

Drimaren

These dyes are less reactive than the triazines because the extra carbon atom reduces the ability of the ring to stabilize a negative charge. The reactivity of the system can be increased by introducing strongly electron withdrawing groups, including the cyano (Reacton) [18], fluoro (Levafix EA) [19], or methylsulfonyl groups (Levafix P) [20]. The pyrimidine ring can also be activated by inserting a carbonyl group between the chromophore and the heterocycle

(Reactophil) [21].

Reactophil

Other diazine moieties are often incorporated into reactive dyes as well, examples being found in the Primazine-P (BASF) [22] and Solidazol (Cassella) dyes [23].

Primazin P

Solidazol

The list of economically attractive reactive heterocyclic intermediates also includes dichloroquinoxalines

(Levafix E) and dichlorophthalazines (Elisian). Anchor systems in both cases are bound to the chromophore via a carbonylamino group, and the reactivities correspond roughly to dichlorotriazinyl dyes.

Levafix E

Elisian

Benzothiazole derivatives with good leaving groups at the 2-position of the heterocycle can also be invoked as reactive anchors. An example with chlorine as the leaving group is the Reatex system:

Reatex (X = Cl)

The reactive group that has had the greatest impact on the market is the 2-sulfooxyethylsulfonyl group (Remazol) [9,24,25]. Treatment with alkali in this case causes the elimination of sulfuric acid to form a vinylsulfonyl moiety that reacts with cotton to give a dye – fiber bond [26]. Describing this as an elimination – addition sequence is not meant to rule out the possibility that the nucleophile attacks the β-carbon directly, without intervention of a vinyl intermediate [27]. Reactive vinylsulfones are also prepared from 2-chloroethylsulfonyl derivatives, which lead to the desired intermediates by elimination of hydrogen chloride.

Numerous derivatives of ethylsulfonyl and vinylsulfonyl groups have been prepared,

C.I. Reactive Black 5 – Remazol Black B

though none have approached the economic importance of the sulfate esters [28, 29].

Dyes containing phosphoric acid groups constitute a class of reactive dyes especially well-suited for polyester – cotton blends (Procion T) [30].

Chrom. – PO_3H

Esterification of the phosphoric acid group with cellulose leads to dye – fiber bonds that are very stable to both acids and bases. However, the required high fixation temperature (210 – 220 °C) in combination with acidic dyeing conditions considerably diminishes the stability of the cotton fibers. (Production of dyes in this category was suspended in 1987 [31]).

2.2. Double-Anchor Dyes

Since the mid-1980s considerable interest has been shown in highly fixing reactive dyes, and the requisite high fixation values have increasingly been achieved with the aid of double anchors. Double-anchor dyes can be divided into two categories: those containing two equivalent reactive groups, and those with mixed-anchor systems.

The first group includes the Procion HE hot dyes, in which two monochlorotriazine units are connected by a suitable bridge (e.g., a diamine). The synthetic approach to these compounds makes it possible to combine two different chromophores in a single system, opening the way to certain color shades that are not easily accessible via a single chromophore [32].

Procion HE

The category of reactive dyes with two equivalent anchors also encompasses products containing two vinylsulfonyl or 2-sulfooxyethylsulfonyl groups. An example is Remazol Black B (Hoechst, **1**), which not only displays a high degree of fixation but is also accessible by a synthetic route that is both simple and economical (see above).

Selective modification of the reactive anchors makes it possible to vary the physical property profile of the dye.

Mixed-anchor systems in reactive dyes were first described by ICI in 1959 [31]. Such "bifunctional" dyes were first marketed by Sumitomo (Sumifix Supra) and Hoechst (Remazol) in the early 1980s. These products are characterized by two anchors with differing reactivities: a more reactive 2-sulfooxyethylsulfonyl group and a less reactive monochlorotriazinyl residue. An example of such a system is Sumifix Supra Yellow 3RF.

Sumifix Supra Yellow 3RF

Warm- and cold-dyeing double-anchor dyes are prepared by incorporating halotriazinyl and vinylsulfonyl reactive anchors. The bond between the triazine ring and a fiber is stable under basic conditions, whereas that to the vinylsulfonyl group is stable to acid. A combination of the two anchor systems therefore produces a dye with good fastness over a wide pH range. Relative to dyes based on dichlorotriazinyl, dichloroquinoxalinyl, or difluorochloropyrimidyl groups, mixed double-anchor dyes show greater acid fastness and more satisfactory behavior with respect to laundry water containing peroxide detergents. The Cibacron C dyes, introduced in 1988, include products in which a fluorotriazine unit bridges a vinylsulfonyl anchor and a chromophore [33]. Here both reactive systems exhibit similar reactivities.

Cibacron C

Other mixed reactive systems have also been patented in addition to the double-anchor dyes so far described, including combinations of monofluorotriazine with difluorochloropyrimidine [34], alkoxychlorotriazine [35], or the 2-(sulfothio)ethylsulfonyl groups [36]. Other examples incorporate a difluorochloropyrimidine ring in conjunction with a vinylsulfonyl group [37].

Despite the growing importance of mixed reactive systems, only the monochlorotriazinyl/vinylsulfonyl and monofluorotriazinyl/vinylsulfonyl dyes described above have become commercially established.

2.3. Multiple-Anchor Dyes

The introduction of more than two anchor groups has only a minor influence on dye fixation characteristics, so multiple-anchor dyes play only a subordinate role in the world market. One example is a multiple-anchor system developed by Cassella, in which cyanuric chloride is bound to an amine with two aliphatic 2-chloroethylsulfonyl chains [38].

3. Chromogens

Virtually every conceivable chromophore has been used in the synthesis of reactive dyes, including monoazo and disazo species (→Azo Dyes), metal complexes of azo dyes (→Metal-Complex Dyes), formazans (→Metal-Complex Dyes, Chap. 6.), anthraquinones (→Anthraquinone Dyes and Intermediates) triphenodioxazines, and phthalocyanines (→Phthalocyanines). The product lines offered by the major dye producers in most cases feature comparable chromophores, differing primarily in the nature of the reactive systems and the particular substitution patterns adopted.

3.1. Azo Dyes [12, 39]

Most reactive dyes fall in the category of azo dyes. Virtually every hue in the dye spectrum can be achieved by appropriate structural modifications (mono- and disazo dyes, combinations involving either single or multiple aromatic and heterocyclic ring systems).

Monoazo dyes with heterocyclic coupling components, such as pyrazolone or pyridone, are yellow to greenish yellow. Other suitable coupling components include aniline and naphthylamine derivatives. Substituted anilines or aminonaphthalenesulfonic acids are employed as diazo components.

C.I. Reactive Yellow 4 – Procion Yellow MX-R

C.I. Reactive Yellow 17 – Remazol Golden Yellow G

A particularly important class of coupling components is the aminohydroxynaphthalenesulfonic acids. Appropriate variation of the disazo component permits the development of shades ranging from orange to black. Orange and scarlet are achieved with I-acid (6-amino-1-hydroxynaphthalene-3-sulfonic acid) and γ-acid (7-amino-1-hydroxynaphthalene-3-sulfonic acid), whereas H-acid (8-amino-1-hydroxynaphtha-lene-3,6-disulfonic acid) and K-acid (8-amino-1-hydroxynaphthalene-3,5-disulfonic acid) derivatives are useful for red to bluish-red hues. Extremely lightfast red shades

are also accessible through disazo dyes ("brown dyes").

C.I. Reactive Orange 1 – Procion Brilliant Orange MX-GS

C.I. Reactive Red 8 – Procion Scarlet MX-G

C.I. Reactive Red 12 – Cibacron Brilliant Red B

When H-acid is used as a double coupling component (as in **1**, where reactive groups are present in both diazo functions) the resulting dye color ranges from blue to black.

Exceptionally lightfast colors are obtained with metal-complexed azo dyes. Copper complexes of *o,o′*-disubstituted azo compounds produce a wide range of colors (yellow, ruby, violet, blue, brown, olive, black).

C.I. Reactive Red 23 – Remazol Red 3B

3.2. Anthraquinone Dyes [40]

Anthraquinone-based dyes are significant because of their brilliance, good lightfastness, and chromophore stability under both acidic and basic conditions. Until quite recently they dominated the market for brilliant blue reactive dyes in spite of their relatively low color strength (molar extinction=15 000) and comparatively high cost. The shades of commercial reactive anthraquinone dyes range from violet to blue. Almost all the important dyes are descendants of "bromaminic acid". This is treated with a reactive amine component, wherein the reactive group may be linked to the amino group by way of various aliphatic or, more often, aromatic bridging units.

C.I. Reactive Blue 19 – Remazol Brilliant Blue R

3.3. Triphenodioxazine Dyes

Dyes derived from the triphenodioxazine ring system (**2**) have been commercially available since 1928 when KRÄNZLEIN and coworkers (Farbwerke Hoechst) discovered dyes with this basic structure augmented by sulfonic acid groups. The unsubstituted triphenodioxazine (which is of no importance as a colorant) was first obtained by G. FISCHER from the oxidation of 2-aminophenol in 1879 [41], and its structure was elucidated in 1890 [42].

2

The first commercial products of this type were sold as blue direct dyes with unmatched tinctorial strength, brilliance, and high lightfastness. An example is C.I. Direct Blue 106 (**3**), which is still on the market today.

3

The commercial success of these products stimulated considerable research activity, especially by the I.G. Farben AG in Frankfurt/Main. This led to a large number of patent applications and several new direct dyes. After World War II research attention shifted toward disperse dyes, cationic dyes, and pigments. In 1952 appropriate treatment of a water-insoluble dichloro derivative led to C.I. Pigment Violet 23 (**4**) [43], whose structure was only later clarified by X-ray structural analysis [44].

4

The triphenodioxazine chromophore was tested in almost every class of dyes, but its only major commercial application was as a direct dye and pigment. Only recently has it been introduced into reactive dyes. For the synthesis and properties of dioxazine dyes, see → Azine Dyes. Dioxazines were investigated in some of the earliest work on reactive dyes in the late 1950s, and they are included in some of the first patents covering reactive anchors and reactive dyes [45]. In particular, compound **5** was invoked as a chromophore, with reactive anchors attached to the free amino groups of the molecule.

Z = reactive anchor

5

The first mixed azo–triphenodioxazine dye containing a monochloro-*s*-triazine group emerged in 1953 [46], with the triazine residue serving not as a reactive anchor but as a link between the two chromophores. In the years that followed, the dioxazine chromophore was also mentioned in most of the patents related to new reactive systems, although none led to a commercial product. At the beginning of the 1970s, the major activity seemed to be concentrated at ICI, leading to several exclusive patents for triphenodioxazine dyes [47]. Within a few years, the first commercial triphenodioxazine reactive dye was introduced: Procion Blue MX-G (C.I. Reactive Blue 163). Other products followed, all designed to achieve brilliant blue shades that could compete with the then-dominant anthraquinone chromophores in certain market segments [48].

The launching of these new products initiated research by other dye manufacturers. Between 1970 and 1979 only about 20 patents appeared on reactive triphenodioxazines and new reactive systems for dioxazine, compared to over 130 patents published in the period 1980–1988. The latter years saw the following new products brought onto the market: Procion Blue T-G, Procion Blue H-EGN, Cibacron Blue F-GF, Levafix Royal Blue E-FR, and 1989 Remazol-Brilliant Blue FB.

Table 1 provides information on a number of commercial triphenodioxazine products and their anchor systems.

By varying the substituents on the orange parent substance **6**, particularly in the positions *para* to the imino groups, its color can be modified. Red to red-violet shades result when X=OH or OR, and blue colors when X=NH_2 or NHR′. A blue shade also results if the external phenyl groups of the dioxazine system are part of an annulated and highly condensed aromatic ring system, for example, pyrene (C.I. Direct Blue 109). For details concerning the influence of chemical structure on color, particularly of dioxazine pigments, see [49].

6

At present, only blue dioxazines are used commercially to color cellulose, where R′ is varied to give reddish to greenish-blue tints. Variation of T has only a minor effect on the shade. Table 2 summarizes observed absorption maxima as a function of various substituents. In particular, blue triphenodioxazines have very high molar extinctions ε, comparable to those of bisazo and phthalocyanine dyes. Until recently, anthraquinone dyes ($\varepsilon = 15\,000$) were predominent in most applications requiring brilliant blue dyes,

Table 1. Examples of triphenodioxazine dyes

Commercial name	C.I. Reactive Identification	Anchor	Year of introduction
Procion Blue MX-G	Blue 163	dichlorotriazine	1975
Procion Blue T-G	Blue 172	phosphonic acid	1978
Procion H-EG	Blue 187	triazylammonium	1979
Procion Blue H-EGN	Blue 198	monochlorotriazine	1982
Cibacron Blue F-GF	Blue 204	monofluorotriazine	1983
Levafix Royal Blue E-FR	Blue 224	sulfatoethylsulfone	1986
Remazol Brilliant Blue FB		sulfatoethylsulfone	1989

but the much stronger triphenodioxazine dyes now represent a less expensive alternative in many applications.

Dioxazine chromophores show a sensitivity to acid and base that is more pronounced in dye solutions than in the fixed dyes. Electron-withdrawing substituents enhance this effect, a major reason why red reactive dyes based on triphenodioxazine have not yet been commercialized [50] even though they are described in most dioxazine patents. Much research and development effort has succeeded in suppressing this sensitivity in the blue dye products currently on the market.

Generally, triphenodioxazine chromophores show a high degree of agglomeration and thus increased substantivity because of their planar arrangement. A higher substantivity causes problems during dyeing, such as unsatisfactory leveling in the exhaust process, tailing from dark to light in the padding process, or limited removal of unfixed dye in the rinsing process. Studies have been directed toward overcoming these problems either with new products displaying less critical substantivity or by control of the substantivity through more suitable dyeing conditions.

The synthetic routes (see below) to almost all dioxazines yield products with a symmetrical structure, resulting in at least two reactive anchors. Indeed, the two dyes most recently introduced (Levafix Royal Blue EFR and Remazol Brilliant Blue FB) are highly reactive double-anchor dyes suitable for both the exhaust and the padding processes. Ecological limits for wastewater are satisfied as a result of a high degree of fixation and low salt requirements in the exhaust process, where the latter also has a positive influence on leveling. These factors and the excellent fastness properties of the dioxazine dyes account for the fact that such dyes are expected to overcome the dominance of anthraquinone-based materials in some segments of the brilliant blue market.

The most important industrial process for synthesizing triphenodioxazines for cellulose fibers involves reaction of two equivalents of an aromatic amine with 2,3,5,6-tetrachloro-1,4-benzoquinone [*118-75-2*] (*p*-chloranil) and subsequent oxidative closure of the ring. All commercially available dioxazines thus contain chlorine atoms at the 6- and 13-positions. The process was discovered in 1911 at Hoechst [51], and its simplicity, coupled with excellent availability of raw materials, was the basis for the commercial success of early dioxazines. In the first reaction step the starting materials are condensed in the presence of an acid-binding agent such as soda ash or magnesium oxide to form the 2,5-diarylamino-3,6-dichloro-1,4-benzoquinone (**7**). Ring closure is then induced by heating either with a metal halide or an acid halide catalyst in a high-boiling solvent (e.g., nitrobenzene) or, in the case of sulfonated dyes, by heating with an oxidant in concentrated sulfuric acid.

In general, the cyclization is a relatively sensitive reaction, and very careful choice of starting materials and reaction parameters is necessary to obtain a product with the desired brilliance and tinctorial strength. The use of oleum in the second step is a significant improvement, because oleum serves not only as a solvent but also as an oxidant, permitting cyclization to proceed at or below room temperature.

Ring closure continued to prove difficult with starting materials containing sulfonic acid groups, which are of great importance in reactive dyes, but this problem was overcome by resorting to a mixture of oleum and persulfate compounds [52]. Later patents describe the use

of halogens [53], manganese dioxide [54], and aqueous hydrogen peroxide [55] as alternatives to persulfate.

The triphenodioxazine chromophore can be converted to a reactive dye by incorporating anchors that are attached to the dioxazine core either directly or via bridging groups. The first patents, like the first commercial products, were based almost exclusively on the use of bridging groups. The usual starting material is 2-chloro-5-nitrobenzenesulfonic acid (**8**), which is reacted with a diamine (**9**).

Table 2. Absorption maxima of triphenodioxazines (6) as a function of substituent groups

T	Y	X	λ_{max}	ε
Cl	SO_2-alkyl	O-alkyl	530 nm	45 000
Cl	SO_2-alkyl	NH-allyl	570 nm	80 000
Cl	SO_2-alkyl	NH-alkyl	612 nm	80 000
Br	SO_2-alkyl	NH-alkyl	613 nm	80 000
Cl	SO_2 —NH-alkyl	NH-alkyl	620 nm	60 000
Cl	SO_2-alkyl	NH-aryl	623 nm	75 000

Reduction produces the *p*-phenylenediamine derivative (**10**), which is condensed with chloranil, and the resulting diarylamino-3,6-dichloro-1,4-benzoquinone(**11**) is isolated, dried, and then cyclized in oleum containing persulfate to yield the desired dye base. The base is converted to a reactive dye by reacting the two primary amino groups with two equivalents of an acylating agent **12**. Typical diamine bridges include 1,4-phenylenediamine-2-sulfonic acid, ethylenediamine, and 1,3-diaminopropane. The reactive anchors are almost always derivatives of *s*-triazines [56–63].

Because of their symmetry, all such triphenodioxazine reactive dyes feature double or even four-fold anchor systems. However, dyes with only one anchor group can be prepared by adding a single equivalent of acylating agent. Most asymmetric products of this type are based on 1,4-phenylenediamine-2-sulfonic acid [64] and characterized by somewhat reddish-blue hues [e.g., **13**, Z=monochloromonomethoxy-*s*-triazine, λ (max.)=560 nm].

Red dioxazines can be synthesized by substituting an amino alcohol for the diamine derivative [65].

Replacing the sulfonic acid **8** with the appropriate carboxy-, carboxamido-, sulfonyl-, or

sulfonamido-4-nitrochlorobenzene leads to analogues described in [66, 67].

Another alternative is attaching the reactive anchor to the dioxazine ring via sulfonamide or carboxamide groups instead of via amine groups, as in **14** [67, 68].

Compound **8** or one of the above-mentioned derivatives can also be reacted with a 2-hydroxyethylsulfonylaniline instead of with a diamine. After reduction of the 4-nitroaniline product **15** followed by condensation with chloranil, the cyclization takes place in oleum where, besides ring closure the 2-hydroxyethylsulfonyl groups are also esterified to β-sulfooxyethylsulfonyl groups [vinylsulfone (VS) groups]. Thus, the reactive anchor is formed concurrently during the cyclization reaction [69, 70].

Other similar fiber-reactive triphenodioxazines are prepared by replacing the sulfonic acid group in **8** with a 2-hydroxyethylsulfonyl group. The starting material here is 4-chloro-3-(2-hydroxyethylsulfonyl) nitrobenzene (**16**), which leads to products containing a VS group bound directly to the dioxazine ring [69, 71] (see top of the next page).

In an analogous reaction, use of a diamine affords dyes with both VS and amino groups. Subsequent acylation of the free amino groups produces the four-anchor system **17** [72].

An entirely different route to reactive dioxazines resembles the synthesis of reactive dyes based on copper phthalocyanine (cf. Sec. 3.5.) [73]. Thus, C.I. Pigment Violet 23 or C.I. Direct Blue 109 is first sulfochlorinated or aminomethylated and the product is then converted into the corresponding reactive dye. However, no compounds based on this approach have yet been commercialized.

Because of the symmetrical nature of the chloranil condensation product **7**, all the syntheses described so far afford exclusively symmetrical triphenodioxazines; i.e., the two phenyl rings fused onto the dioxazine skeleton bear the same substituents. An elegant synthesis for an asymmetric chloranil condensation product has not yet been developed. One possible approach has been described starting with 2-methoxy-3,5,6-trichloro-1,4-benzoquinone [74], but its feasibility is uncertain [75].

A *mixed chloranil condensation* [37] involves reacting two different amines with chloranil to give a mixture of three condensation products, two of which are symmetric (**18**, **19**) and one asymmetric (**20**). Ring closure then yields a mixture of dyes.

Z = reactive anchor **17**

Almost all of the amines described earlier can be used in this condensation. In the case of dye bases with amino groups, reactive anchors can be subsequently introduced by acylation [76].

3.4. Formazan Dyes [12,77]

Copper complexes of the formazan dye series (→Metal-Complex Dyes, Chap. 6.) are another alternative to reactive anthraquinone dyes, producing red to greenish-blue shades. Like triphenodioxazine dyes, copper formazans exhibit high molar extinctions (ε=25 000–30 000). These materials are derived from 1-(2-hydroxyphenyl)-3-phenyl-5-(2-carboxyphenyl)-formazan **21**, in which all three rings are capable of supporting groups that increase the compound's reactivity and solubility.

21

3.5. Phthalocyanine Dyes [12,39]

The water-soluble reactive phthalocyanine dyes (→Phthalocyanines) yield brilliant turquoise and green colors not available from any other dye category. The most important reactive phthalocyanine dyes contain copper or nickel as their central atom; they are substituted with sulfonic acid groups and also with reactive groups joined via sulfonamide bridges.

C.I. Reactive Blue 15 – Cibacron Turquoise Blue GF-P

4. Synthetic Procedures

The synthesis of selected reactive dyes is illustrated by the following examples taken from the patent literature.

Example 23 from EP 84,318 (Bayer, German Prior. of 01/15/82). 61.1 g of dye (obtained by coupling diazotized 4-(2-sulfooxyethylsulfonyl)aniline with 1-amino-8-naphthol-3,6-disulfonic acid at pH 1 – 2) is coupled at pH 6 – 7 with a diazonium compound synthesized from 33.7 g of the condensation product derived from 18.8 g of 1,3-diaminobenzene-6-sulfonic acid and 17 g of 2,4,6-trifluoro-5-chloropyrimidine. The crude material is salted out of solution, isolated, dried, and pulverized to a dark powder (**22**). This product gives a blue solution in water and dyes cotton a marine blue to black color [78] (see below).

Example 1 from EP 28,788 (Hoechst, German Prior. of 11/10/79). 32.0 parts of the hydrazone from 2-carboxyphenylhydrazine-4-sulfonic acid and benzaldehyde are suspended in 200 parts of water at 20 – 25 °C. The solid is dissolved by adding 50 % aqueous sodium hydroxide to obtain pH 6.5 –7.0. This solution is added at 5 – 15 °C to the aqueous diazonium salt solution obtained from a typical aqueous diazotization of 37.7 parts 4-(2-sulfooxyethylsulfonyl)-2-aminophenyl-6-sulfonic acid. The mixture is then dripped during 15 min into 100 parts by volume of an aqueous solution of 1 mol/L copper sulfate (at 10 – 15 °C) while the pH is maintained at 5.5 – 6.5 with 18 parts of soda. The reaction mixture is stirred for an additional hour at room temperature to ensure complete coupling, after which the pH is adjusted to about 1 with 30 parts by volume of conc. hydrochloric acid.

The strongly acidic solution is further stirred for one hour and then neutralized with either sodium carbonate or potassium carbonate to pH 5.5. The copper – formazan complex is salted out along with sodium or potassium chloride, filtered, washed with dilute aqueous sodium or potassium chloride solution, and dried at 80 °C. A dark powder results which gives a dark blue solution in water. It consists of an electrolyte-containing powdered sodium or potassium salt of the following acid:

This compound is a very effective dye, rendering cotton and regenerated cellulose fibers a clear blue shade on prolonged treatment in the presence of an acid-binding agent. After a 10 minute soapy water wash the resulting colors prove to be very light- and waterfast [79].

Example 3 from EP 248,493 (Hoechst, Priority from 08/19/86). A triphenodioxazine compound is synthesized starting with 54 parts of aniline derivative **23** dissolved in 500 parts of water at pH 6.

22

23

This solution is first warmed to 60 °C and then added in portions to 19 parts of chloranil at pH 6 – 6.5. The mixture is stirred for 3 h, after which the precipitated product is filtered, washed with water, and dried at 80 °C under vacuum.

Cyclization of the condensation product to the triphenodioxazine entails slowly adding 20 parts of the starting material at 20 °C to 220 parts of 10 % oleum with stirring until solution is complete. The temperature is carefully maintained at 20 – 25 °C while 11.5 parts of sodium peroxodisulfate are added. After one hour of further stirring the mixture is poured onto ice. The resulting suspension is adjusted to pH 1 – 1.5 with calcium carbonate and treated with sodium carbonate until the pH reaches 5.5. Calcium sulfate is then removed by filtration and washed with water. The combined filtrates are concentrated by evaporation or spray drying to give the desired product.

A sodium salt based on the following structure is obtained as a powder that also contains sodium sulfate:

This material offers very good reactive dye properties [$\lambda_{(max)}$=612 nm] with respect to the cited materials, especially cellulose fibers (e.g., cotton), producing a strong blue shade with good fastness properties [80].

Synthesis of 24 [57]**:**

24

Chloranil Condensation Product. To a solution of 16 g of 4-(2′-aminoethylamino)-aniline-3-sulfonic acid (for synthesis, see [59]), in 200 mL of water is added a suspension of 6.1 g of chloranil in 12 mL of water and 5 mL of acetone. The pH is brought to 5.5 with 60 g of 10 % aqueous sodium acetate and the mixture is stirred at pH 5.3 – 5.5 for 2 h at 45 – 50 °C. After cooling to 10 °C, the precipitated brown solid is filtered, washed with 300 mL of acetone, and dried at 60 °C.

Dye Base. The chloranil condensation product (7.5 g) is added to 150 g of 25 % oleum, stirred for 10 min at 50 °C, cooled to 20 °C, and stirred another 30 min. The reaction mixture is then poured onto 500 g of an ice – water mixture, and the precipitate is filtered and washed with 200 mL of cold water. For purification, the crude product is dissolved at pH 11 in 7 g of 40 % sodium hydroxide solution and then reprecipitated with 30 g of a saturated aqueous solution of potassium acetate. The purified product is filtered, washed with 10 % aqueous potassium acetate and 800 mL of ethanol, and then dried at 60 °C.

Reactive Dye. A solution of 3.5 g of aniline-3-sulfonic acid in 50 mL of water containing 10 g of 2 mol/L sodium hydroxide solution is added to a suspension of 4 g of cyanuric chloride in 40 mL of water and 40 mL of acetone at 0 – 5 °C while the pH is kept between 6.0 – 7.0 with more sodium hydroxide. After 1 h the excess cyanuric chloride is removed by filtration and the filtrate added to a solution of 3.5 g of the dye base in 200 mL of water. The resulting mixture is heated for 8 h at 45 – 50 °C with the pH maintained at 9.0 – 9.2. After cooling to room temperature, the product is salted out with 25 wt % sodium chloride solution, filtered, washed with saturated sodium chloride solution, and dried at 60 °C.

5. Uses

5.1. Forms of Supply

In the past, reactive dyes were marketed mainly as powders, but other physical forms of these products have gained in importance. Dyes are now expected to be dedusted in order to minimize hygiene-related problems in the workplace. Moreover, the growing trend toward automated dye works has encouraged the development of more readily meterable products. Reactive dyes should also display good cold water solubility. These demands are all met by liquid dyes–highly concentrated, aqueous solutions–and by solids supplied in the form of pourable granules and finished powders [81–85].

5.2. Dyeing Processes

The most important application of reactive dyes is in the dyeing and printing of cellulose fibers and cellulose fiber-based materials. Wool, silk, and synthetic polyamide fibers also lend themselves to reactive-dye treatment. The process of dyeing cellulose requires the presence of a base (e.g., sodium carbonate or sodium hydroxide) together with an electrolyte, usually sodium chloride or sodium sulfate, which increases the fixation yield. The optimal dyeing temperature and pH is a function of the dye's anchor system. Thus, the optimal temperature for a "cold dye" is ca. 30 – 50 °C, whereas that for a "hot dye" is ca. 70 – 98 °C.

There are three major variants of the dyeing procedure for reactive dyes. The dominant method is still the *discontinuous exhaust dyeing process*, but the *semicontinuous pad-batch process*, and the *continuous process* are gaining in importance.

Improvements in the exhaust process itself and the development of new equipment have led to improved process safety and lower costs. The conventional exhaust dyeing methods are the "all-in" process, which means that all the dyebath components are introduced at room temperature and fixation is initiated by slow heating until the correct dyeing temperature is reached, and the "preconditioning method," in which an electrolyte is added to facilitate absorption of the dye onto the fibers in the absence of alkali. Base is added subsequently in portions at the dye temperature, causing fixation of the color onto the material. In a modern facility, alkali and salt may be metered and added to the bath automatically. This increases the extent of levelling, and it also reduces the amount of salt required and contributes to process safety. Reduced salt load in the process wastewater is important from an ecological standpoint [86–88].

In the *semicontinuous pad-batch process* the fabric is brought in contact with the dye solution and fixation is allowed to occur over several hours before the dyed material is rinsed, washed, and dried [89].

The *pad-steam procedure* is the most important of the continuous methods. Here the fabric is dyed and washed in a single process. The dye solution is padded onto the material, and drying and fixation are accomplished through treatment with hot air or steam at elevated temperature prior to washing.

A reactive dye constitutes only one of several components in the dye paste that is applied to cellulose fibers during a textile printing operation. Such a paste also includes a thickening agent (usually an alginate), urea, alkali, and an oxidant. Fixing is usually accomplished by a steam or dry-heat method. Of increasing importance is the *two-phase* printing process based on alkali-free print pastes. In this case the alkali required for fixation is padded onto the fabric after drying. Fixing is achieved subsequently either through a steam process or by cold dwelling.

In the application of reactive dyes to wool or silk attention must be directed to the sensitivity of these materials to base. Silk can be dyed by the exhaust process in a weakly basic medium at 60 °C, but the dyeing of wool is usually carried out in a weakly acidic bath [90, 91].

1. Introduction

In 1905, Langley laid the ground work for the idea of differing adrenergic receptors [1–3] and suggested that the excitatory and inhibitory effects of sympathetic nerve stimulation or of giving adrenaline could be explained by the concept that "a cell may make motor or inhibitory receptive substances or both, and that the effect of a new impulse depends upon the proportion of the two kinds of receptive substance which is affected by the impulse" [4]. Sir Henry Dale remarked that the "...cardioaccelerator effect of adrenaline ... is not abolished by doses of ergot sufficient to reverse the effect on the blood pressure," while the noncardiac excitatory actions of adrenaline such as vasoconstriction were blocked by ergot, the inhibitory effects such as smooth muscle relaxation were not [5]. Dale almost anticipated Ahlquist's [6] simple division of catecholamine responses into α- and β-effects [1]. Barger and Dale [7] formulated the problem more in terms of receptors. They suggested that the most notable feature of the catecholamines they studied was "the more or less strict localization of their action to cells innervated by a certain morphological system, on which cells they act when present in very high dilutions. There must evidently be something in these cells, or connected with them and them only, which has a strong affinity for these amines." While acknowledging the possible importance of receptive side-chains they concluded "it by no means follows that the peculiar distribution of the action of nicotine or the sympathomimetic amines depends on the existence of specific chemical receptors in the cells peculiarly sensitive to them, as supposed by Langley" [7]. However, as Black observed: "Dale never referred to receptors again in his writings. Dale's attitude seems to have had a powerful effect in delaying the introduction of the idea of receptors into pharmacological teaching and his impact was still dominant when Ahlquist's paper appeared in 1948."

In 1933, Cannon and Rosenblueth [8] suggested that a transmitter substance was released by sympathetic nerve endings which combined with either excitatory (E) or inhibitory (I) substances to form sympathin (E) or sympathin (I). The complexes formed then acted on tissues or were released into the blood in varying concentrations. This sympathin theory explained sympathetic effects in hormone terms rather than receptors. The ideas of Ahlquist were seen to be revolutionary against this background.

α- and β-Receptors. Ahlquist reported the potency of six sympathomimetic amines in 1948 [6]. The amines fell into two distinct classes, which he explained by the existence of two types of receptor, α and β. The excitatory effects (vasoconstriction, stimulation of

10.1002/14356007.a22_665

the uterus, nictitating membrane, ureter, and dilator pupillae) and one inhibitory action (intestinal relaxation) were termed *α-effects;* at the α-receptor adrenaline was the most potent followed by noradrenaline. Most of the inhibitory actions (vasodilation, inhibition of uterine and bronchial smooth muscle), and one excitatory action (myocardial stimulation) were called *β-effects;* at the β-receptor isoprenaline was the most active, adrenaline was third, and noradrenaline least effective. AHLQUIST therefore realized that receptors could either be excitatory or inhibitory, i.e., one receptor type did not have just either excitatory or inhibitory effects.

The adrenergic receptors have been further divided into α_1-, α_2-, β_1-, and β_2-receptors according to the properties of stimulant (agonist) drugs and blocking (antagonist) drugs [9, 10]. These receptors mediate various physiological effects, see Table 1.

Table 1. Adrenoceptors

Organ	Receptor	Physiological effect
Heart	$\beta_1 > \beta_2$	stimulation of contractility and heart rate
Smooth muscle of bronchi	β_2	bronchodilatation
Blood vessels smooth muscle	α_1 α_2	vasoconsttriction vasoconstriction
	β_2	vasodilatation
Skeletal muscle	β_2 β_2	glycogenesis tremor
Genitourinary tract smooth muscle	α_1 β_2	muscle contraction muscle relaxation
Fat tissue	α_2 β_1	inhibition of lipolysis stimulation of lipolysis
Platelets	α_2	aggregation
Liver	α_1 β_2	glycogenolysis glycogenolysis glycogenolysis
Pancreas	α_2 β_2	inhibition of insulin release stimulation of insulin release
Sympathetic nerve terminals (presynaptic)	α_2 β_2	inhibition of noradrenaline release stimulation of noradrenaline release

Dichloroisoprenaline (DCI) was found to block the bronchodilator, vasodilator, and the inhibitory actions of adrenaline [11, 12]. MORAN and PERKINS then reported the blockade of the cardiac stimulant effects of adrenaline by DCI [13], and they suggested that DCI acted on the β-receptor described by AHLQUIST. They also proposed that the compounds that blocked the effects of adrenaline be termed according to the receptor for which they had the greatest affinity; they introduced the terms α- or β-adrenergic blocking drugs. Although DCI was shown to block the adrenaline-induced increase in forearm blood flow [14] and control the tachycardia [relatively rapid heart action whether physiological (as after exercise) or pathological] and arrhythmias associated with the removal of pheochromocytoma [15], its clinical potential was not appreciated.

Development of Clinically Useful β-Blocking Drugs. BLACK paid special attention to the problem of coronary heart disease. He thought that rather than trying to increase coronary artery flow, as was then usual, a better idea might be to reduce oxygen consumption. He appreciated the clinical value of developing compounds to inhibit the sympathetic innervation to the heart. He led a team of scientists at ICI who put this idea into practice. This was at a time when the sympathetic system was only regarded as essential for the flight and fight reaction and the value of inhibiting it was not generally appreciated [2].

Research at ICI led to the introduction of pronethalol [16] which was found to be effective in angina pectoris [17–19], arrhythmias [20], pheochromocytoma [21], and in the treatment of hypertension [22]. Pronethalol's evaluation and use was delayed until 1964 because of the development of tumors in mice [23]. Most of the pioneer work with β-adrenoceptor blocking drugs was performed on this drug [24].

2. Pharmacodynamics

Differences in the pharmacological actions of β-adrenoceptor blocking drugs can be used as a basis for classification. They may be nonselective (i.e., they act on all the β-adrenergic receptors), have a selective action on the β_1-receptors, and possess vasodilator or α-receptor blocking properties. Besides the blocking activity they may be further subdivided according to the presence or absence of a stimulatory effect, i.e., intrinsic sympathomimetic activity (ISA) or partial agonist (stimulant) activity. Finally, a membrane stabilizing activity (MSA) or local anesthetic action may also be considered [25–27] (Table 2).

Table 2. Classification of beta-adrenoceptor blocking drugs

	Partial agonist effect (intrinsic sympathomimetic effect)	Membrane stabilizing effect (quinidine effect)
Division I: Nonselective ($\beta_1+\beta_2$) block		
Group I		
Oxprenolol	+	+
Alprenolol		
Group II		
Propranolol	–	+
Group III		
Pindolol	+	–
Carteolol		
Group IV		
Sotalol	–	–
Timolol		
Nadolol		
Division II: β_1 selective		
Group I		
Acebutolol	+	+
Group III		
Practolol	+	–
Celiprolol		
Group IV		
Atenolol	–	–
Betaxolol		
Metoprolol		
Bisoprolol		
Division III: Nonselective block and α block		
Group II		
Labetalol	–	+
Carvedilol		

β_1-Selective drugs were previously termed cardioselective, reflecting their pronounced effect on the heart in preference to other tissues, however as both β_1- and β_2-receptors are found in the heart the term "cardioselective" is inaccurate.

Competitive inhibition is shown by all presently available β-blocking drugs. The receptor occupancy is therefore dependent on the ratio between the concentration of agonist and antagonist. The agonist may be the natural neurotransmitter (noradrenaline), an endogenous stimulant, or an exogenous (administered) β-stimulant such as isoprenaline. It is possible to construct a series of dose – response curves to isoprenaline in the presence of a β-adrenoceptor antagonist. The dose – response curves demonstrate a parallel shift to the right as the dose of antagonist increases, the same maximum response is obtained on increasing the dose of the agonist, isoprenaline [28].

Blockade of Endogenous Sympathetic Activity and Hemodynamic Effects. When sympathetic activity is low (e.g., resting supine or asleep), there is a dose-related fall in heart rate on administering *β-blocking drugs without ISA* (e.g., propranolol) [29]. All β-blockers reduce exercising heart rate when sympathetic tone is high [30]. Acute intravenous administration of propranolol reduces heart rate and cardiac output, but increases peripheral resistance, therefore resting blood pressure is not initially affected [31]. With oral administration, heart rate and cardiac output are reduced [32, 33], but there is also a fall in peripheral resistance and blood pressure falls [32, 34, 35]. Changes in heart rate and cardiac output for non-ISA drugs are similar whether they are β_1-selective or nonselective [36, 37].

β-Blocking drugs with ISA reduce heart rate less than the non-ISA drugs, some have no effect on resting heart rate [38, 39]. At modest levels of exercise, reduction in the increase of heart rate on exercising may be similar with both ISA and non-ISA drugs [38]. At high levels of exercise, however, drugs with ISA (at maximum dosage) produce less of a reduction of exercise tachycardia than non-ISA drugs [30, 40, 41]. The increase in exercise heart rate remaining after a non-ISA drug has been given is largely a result of the withdrawal of the slowing effect of the vagus. Whereas the increase in heart rate may be similar with exercise, the possession of ISA means that the actual heart rate is higher, as the result of the modest sympathetic stimulus from ISA. The changes in cardiac output after the administration of β-blocking drugs usually parallels alterations in heart rate.

When given at low levels of sympathetic activity (i.e., at rest), drugs with ISA induce less reduction in cardiac output, as has been shown with pindolol [39, 41], practolol [36, 39], and oxprenolol [42]. Peripheral resistance increases only slightly and can even fall.

The rise in blood pressure during dynamic exercise is reduced by β-blockade [43]. The rise in blood pressure due to isometric exercise is not greatly modified by β-blocking drugs, although the final pressure may be reduced because of a decline in baseline values [44, 45]. There was

evidence of a smaller rise in diastolic pressure with atenolol than with propranolol, pindolol, or oxprenolol with isometric exercise [46] and less after metoprolol than following propranolol [47].

β_1-Selectivity. The efficacy of β-blocking drugs in inhibiting the effect of isoprenaline, a nonselective (i.e., acts at both β_1- and β_2-receptors) β-stimulatory drug on the heart shows considerable variation. For equivalent inhibition of exercise tachycardia, far less antagonism of the cardiac effects of isoprenaline is seen with the β_1-selective drugs than with the nonselective agents, with or without ISA [48–52]. The reason for this discrepancy appears to be the presence of cardiac β_2-receptors in addition to β_1-receptors [9,51,53]. The fact that both nonselective and β_1-selective drugs are more equivalent in terms of inhibition of exercise tachycardia indicates that exercise tachycardia (i.e., sympathetic nerve stimulation) is mediated via β_1-receptors.

A rise in blood pressure, involving the liberation of adrenaline, occurs with smoking [54] or insulin hypoglycemia [55] and tends to be aggravated when the β_2-dilator action of adrenaline is antagonized. Antagonism of the dilator component of adrenaline by nonselective β-blocking agents converts the action of adrenaline into that of noradrenaline [56]. It therefore might be expected that pressor responses involving the liberation of adrenaline are differently affected by β_1-selective blockade. For example, the pressor responses to a combination of coffee and cigarettes is attenuated by atenolol (a β_1-receptor blocking drug) whereas neither oxprenolol or propranolol, both nonselective (i.e., block β_1- and β_2-receptors) have any effect [57]. There is less increase in airway resistance with β_1-blockade than with nonselective blockade as might be expected from the predominance of β_2-bronchodilator receptors. This is the most important difference of the β_1-selective agents from the nonselective drugs [58–60]. However, even the β_1-selective drugs must be regarded as a potential risk in asthmatic patients [60].

There is also evidence that β_1-selective drugs produce a lower increase in low-density lipoproteins (LDL) and a lower decrease in high-density lipoproteins (HDL) than nonselective agents [61]. Additionally β_1-selective agents, un-like nonselective drugs, do not appear to prolong the action of insulin hypoglycemic drugs [61,62]. Finally β_1-selective agents do not impair the metabolic changes in muscles associated with exercise to the degree seen with other β-blocking drugs [61].

Intrinsic Sympathomimetic Activity (ISA). The most marked property of a β-blocking drug that possesses ISA is its central hemodynamic effect [63]. Such a drug produces a lower fall in resting heart rate [38,64], cardiac ouput [39,65], and peripheral blood flow [36, 66,67] than a drug without ISA. If the level of sympathetic tone is low enough (e.g., during sleep) and the amount of ISA is sufficient, the drug may even increase the heart rate. If the drug possesses ISA at the β_2-receptor (e.g., pindolol), then peripheral vasodilation due to stimulation of β_2-vasodilator receptors may also be important [68]. At high levels of exercise and full doses, a β-blocking drug with ISA gives a lower reduction in heart rate than one without [52,60]. In patients with asthma, the modest, β-stimulant action of an ISA drug on bronchial smooth muscle is not important and is more than offset by β-blockade – these patients are potentially very sensitive to any receptor blockade which worsens their asthma [69]. Chronic stimulation by a β-blocking drug with ISA reduces the number of β-receptors and thus when the drug is stopped abruptly there is no post-β-blocking drug hypersensitivity in contrast to non-ISA agents (which increase the number of β-receptors) [27,70–72]. Finally, there is evidence that drugs with ISA do not interfere as much in metabolic processes, particularly lipid metabolism [61], and the liver metabolism of other drugs [73].

Combination of β- and α-Blockade or Vasodilator Activity. *Labetalol* was the first combined β- and α-receptor blocking drug [28], and it has been extensively evaluated in hypertension [74,75]. *Medroxalol* also possesses both β- and α-blocking properties [76], and probably an additional vasodilator effect mediated by β_2-adrenergic stimulation [77,78]; it is an effective drug in hypertension [79]. *Carvedilol* has α_1-blocking properties and some additional vasodilator action [80–87]. *Celiprolol* has β_1-blocking properties and a vasodilatoy action which seem to be a combination of some β_2-

stimulatory action; also a direct vasodilator action [88, 89].

Several drugs which possess β-blocking and vasodilator activity have been evaluated. *Prizidolol* has been withdrawn because of animal toxicity [90]. *Bucindolol* and similar drugs are still being evaluated [91, 92].

3. Pharmacokinetics

The β-blocking drugs fall into two broad groups in terms of their elimination. *Lipid-soluble drugs* undergo extensive first-pass metabolism in the liver and readily penetrate the brain. *Water-soluble drugs* are excreted unchanged in the urine and have low brain penetration.

Lipid-Soluble Drugs. The liver metabolism of the lipid-soluble β-blocking drugs (e.g., alprenolol, metoprolol, labetalol, oxprenolol, propranolol) differs and their plasma concentration therefore varies between individuals after the same oral dose [93–95]. The relationship between the dose and the area under the plasma concentration curve (AUC) varies at low dosages. For example, at lower doses (e.g., 200 mg alprenolol [96] or 40 mg propranolol [97]) alterations in AUC are nonlinear and increases are lower than at higher dose levels. Oxprenolol, on the other hand, also undergoes hepatic metabolism but shows a linear, dose-related increase in plasma concentration [98]. Although the first-pass effect becomes saturated at high doses, systemic bioavailability does not exceed 50 %, even with larger doses of propranolol [99]. Liver metabolism and therefore steady-state plasma concentration are dependent on hepatic blood flow [94, 100]. Conditions that reduce liver blood flow (e.g., congestive heart failure, cirrhosis) lower hepatic clearance and prolong the drug half-life. Drugs such as propranolol, which reduce cardiac output and hepatic blood flow, slow their own metabolism and that of any other drug metabolized by the liver. Thus, while single doses have a plasma elimination half-life of 2 – 3 h, chronic administration may prolong this to 6 h.

The lipid solubility of pindolol is high but only about 50 % is metabolized in the liver and therefore first-pass effects are less important [101]. In the case of bisoprolol, about half is also eliminated via liver metabolism and half excreted via the kidney [102]. The intrinsic sympathomimetic activity of pindolol and oxprenolol means that they have less effect on cardiac output at rest, and therefore plasma half-lifes should be similar after acute and chronic administration [103].

Water-soluble drugs are eliminated in the urine unchanged (e.g., atenolol and sotalol) or as active metabolites. Half-life increases with renal insufficiency [104, 105]. The water-soluble β-blockers have more predictable plasma concentrations than the lipid-soluble drugs because they are independent of variable liver metabolism. Plasma concentrations of atenolol vary two- to five-fold between individuals [106, 107], much less than, for example, propranolol.

Distribution. The lipid solubility of drugs affects their volume of distribution within the body, which may vary about eight-fold (0.7 and 5.6 L/kg for atenolol and propranolol, respectively) and mostly exceeds the physiological body space [108]. There is a slight reduction of volume of distribution in renal failure or in the elderly (e.g., with sotalol) [109]. Drugs with a volume of distribution greater than the total body water indicate that concentration occurs in certain tissues (particularly lung, liver, and heart) [110, 111]. Drugs with high lipid solubility (e.g., alprenolol and propranolol) show rapid penetration across the blood – brain barrier [108]. The lung is a major organ of deposition for propranolol [110]. Although lipophilic substances have larger volumes of distribution than the water-soluble drugs, they have shorter plasma elimination half-lifes because drug clearance occurs via the liver rather than the kidneys and the liver has a greater elimination capacity [108].

4. Clinical Uses of β-Adrenoceptor Blocking Drugs

The β-adrenoceptor blocking drugs are widely used, particularly in cardiovascular medicine, and have markedly changed therapeutic practice [24].

Ischemic heart disease involves an imbalance between the use and supply of oxygen, this is temporary and reversible in angina pectoris, but sufficient in myocardial infarction to give myocardial necrosis. Angina pectoris was one of the original indications for β-adrenoceptor blocking drugs, and they have become highly effective prophylactics [75], see also → Coronary Therapeutics, Chap. 4. There are two approaches to therapy, vasodilation of coronary vessels (e.g., glyceryl trinitrate) or reduction of oxygen usage by the heart. β-Blocking drugs reduce cardiac oxygen demand, particularly during excercise and other forms of sympathetic stress such as emotion. They reduce heart rate, systolic blood pressure, and ventricular contractility. Although ventricular size increases, thus increasing oxygen consumption, this only partly offsets the benefit. There is an overall fall in coronary flow, presumably due to an autoregulatory effect. β-Blocking drugs redistribute blood flow in ischemia, blood flow is increased in vulnerable areas because the relatively well perfused myocardium uses less oxygen. In addition to these hemodynamic effects, β-blockers lower the free fatty acid concentration which improves myocardial utilization of carbohydrates.

Silent Ischemia [112]. Most episodes of silent ischemia are not associated with pain and are often hemodynamically indistinguishable from overt ischemic events. They may be preceded by an increase in heart rate. β-Blockade reduces the number of episodes.

Myocardial Infarction. β-Blocking drugs are useful in treating myocardial infarction [113]. Acute intravenous administration reduces infarct size by ca. 25 %. Blockade of the β_2-receptors appears to be the important component. The number of patients with threatened infarction who develop frank infarction is also probably significantly reduced [114, 115]. Effects on mortality in acute studies have been less impressive than in late intervention studies. Large-scale studies have indicated a significant reduction in vascular mortality of about 15 % in groups treated with metoprolol [116] and atenolol [117]. The value of intravenous followed by oral β-blockade is probably maximized if intravenous administration occurs within 12 h of the onset of pain; after one year, a significant reduction in mortality is still apparent [117, 118]. The incidences of reinfarction and cardiac arrest are significantly decreased (15 – 18 %) by early intravenous β-blockade. There have been some problems with morbidity or adverse reactions with these early-entry studies, but while bradycardia and hypotension can occur they rarely require active intervention. Cardiogenic shock and heart fail-ure, even in high risk patients, are uncommon [116, 117].

The long-term administration of β-blockers after myocardial infarction (secondary prevention studies) indicates that β-blockers decrease total mortality by about 25 %. This benefit derives from β_1-blockade, and both β-selective and nonselective agents give similar benefits [115]. Pooled analysis showed a 10 % decrease in mortality with β-blockers possessing ISA, significantly less than the 30 % with β-blockers without ISA [115]. A positive relationship between the decrease in resting heart rate on β-blocker treatment and the decrease in mortality has been suggested: β-blockers with moderate to high ISA have little effect on resting heart rate [119].

Hypertension. The β-adrenoceptor blocking drugs are first-choice drugs for treating hypertension [120] and have been in use since the early 1960s (→ Antihypertensives, Chap. 4.2.3.). Blood pressure falls regardless of the presence or absence of β_1-selectivity, intrinsic sympathomimetic activity, and membrane activity. β_1-Blockade is the important factor and a high level of pure β_1-stimulation prevents the fall of blood pressure. The membrane-active, non-β-blocking isomers of β-blocking drugs are without antihypertensive activity [121, 122].

Attempts to explain the hypotensive effect of β-adrenergic blocking drugs include a direct action on the central nervous system (CNS), blocking of adrenergic neurones, antirenin activity, an increase of vasodilator prostaglandin concentrations, and secondary effects resulting from pressor stimuli caused by reduction in cardiac activity consequent to β-blockade. However, the exact mode of action remains unclear [120], and may not be the same in all patients.

The greatest attention has been given to correlation of the effect of β-adrenoceptor blocking drugs on blood pressure and renin levels. Renin acts on angiotensinogen to form an-

giotensin I, a blood pressure-regulating peptide (→ Peptide and Protein Hormones, Chap. 5.1.). Patients with high renin levels responded best to propranolol, whereas patients with normal renin levels had a lower fall in blood pressure [123]. The correlation between renin levels and response of blood pressure with a variety of β-adrenoceptor blocking drugs is described [123, 124]. A relatively low dose of propranolol (160 mg/d) readily lowered the blood pressure in high-renin patients, but higher doses (320–960 mg/d) were needed to lower the blood pressure in low-renin patients, independent of effects on renin levels. However, other investigators have not found a correlation between renin levels and response to β-adrenoceptor blocking drugs (propranolol [34, 125–127], pindolol [127, 128], sotalol [129], timolol [130], or metoprolol [131, 132]).

The efficacy ofβ-adrenoceptor blocking drugs is similar to that of other antihypertensive drugs (diuretics, angiotensin converting enzyme inhibition, and calcium antagonists) but give better control of the exercising blood pressure. The β_1-selective agents have a slightly greater antihypertensive effect than the nonselective agents [24]. It had been hoped that the use of β-blocking drugs in the treatment of hypertension would reduce the incidence of myocardial infarction (primary prevention) because a reduction in further infarction had been demonstrated when β-blocking drugs were given after myocardial infarction. The result of studies, however, is not clear cut. Investigations in younger patients [133–135] suggest β-blockers may have some benefit, but in elderly patients no benefit was seen [136].

Orthostatic Hypotension. There has been some attempt to treat the excessive fall in blood pressure that occurs in the upright position (orthostatic hypotension) with β-receptor blocking drugs, the rationale being that β_2-blockade would allow the unopposed α- constrictor activity of circulating adrenaline to raise the blood pressure. Some reports show good results with pindolol (moderate ISA) [137] or propranolol, but others have not found either drug effective [138]. Some benefits have been obtained with agents with ISA (e.g., prenalterol or xamaterol) [139], which may also give additional benefit by maintaining or increasing cardiac output.

Dissection of the Aorta. The tearing of the wall of the aorta, dissection, is a highly lethal condition: without treatment 90 % of patients die within three months of the event [140]. Medical treatment is aimed at lowering blood pressure, it would also be useful to reduce the speed and force of contraction of the heart. β-Blockade should be administered intravenously. The blood pressure, if high, may be acutely lowered with, for instance, nitroprusside [41]. For distal dissections, long-term medical therapy rather than surgery may be desirable, the goal being good antihypertensive control and a decrease in ventricular ejection velocity [141]. β_1-Blockade is required and thus the choice of β-blocker is unimportant, unless there is a contra-indication to β_2-blockade (e.g., asthma) in which case a β_1-selective agent should be cautiously used. Late survival can be expected to be reduced from 90 % in untreated patients to about 40 – 50 % treated by drugs or surgery [141, 142].

Valvular Disease. In mitral valve prolapse, oral propranolol reduces the fall in blood pressure on standing associated with faintness and syncope [143]. β-Blockade reduces the pressure gradient across the mitral valve in mitral stenosis by increasing the time available for diastolic filling [24]. There have not been many studies on aortic valvular disease: administration of 100 mg atenolol for one week improved exercise tolerance and reduced exercise-induced angina and dyspnea in patients with aortic stenosis.

Cardiac Arrhythmias. The effect of β-blocking drugs varies considerably according to the type of cardiac arrhythmia. Catecholamines accelerate the rate of diastolic depolarization of automatic pacemaker cells and therefore increase the heart rate, accelerate the conduction process, and shorten the refractory period of ventricular cells. They therefore predispose the heart to extrasystoles and lower the threshold to ventricular fibrillation [144]. The β-adrenoceptor blocking drugs inhibit these influences [145], but may also indirectly modify processes which predispose to arrhythmias such as myocardial ischemia or thyrotoxicosis [24]. See also → Antiarrhythmic Drugs.

The direct antiarrhythmic property of β-blockers occurs via β_1-blockade [24]. β_1-

Selective and nonselective agents are equally effective in inhibiting stress-induced arrhythmias. Membrane-stabilizing activity is relevant only at very high dosages [146] (e.g., propranolol > 640 mg/d) where a quinidine-like antiarrhythmic effect might contribute [24]. Sotalol possesses additional antiarrhythmic properties (i.e., it prolongs the duration of the action potential) and so differs from the other β-blockers [147, 148].

Supraventricular Tachycardias. Abnormal (ectopic) atrial tachycardias are frequently associated with increased sympathetic activity and may respond well to a β-blocker [149]. Multifocal atrial tachycardia associated with pulmonary disease is usually unresponsive. Intravenous β-blockade is often effective in paroxysmal (sudden) supraventricular tachycardias that are not due to pre-excitation. Additionally vagal maneuvers are often more successful in the presence of a β-blocker [150]. Chronic oral administration of β-blockers often prevents the onset of these arrhythmias, particularly if the arrhythmia is precipitated by emotion or exercise [144]. The effective refractory period of accessory pathways involved in supraventricular tachycardias arising from preexcitation (e.g., Wolff – Parkinson – White Syndrome, WPW) is only influenced by sotalol. Nevertheless by altering conduction and refractoriness in the atrioventricular (AV) node or suppressing initiating premature beats, intravenous or oral propranolol can be very effective in preventing or suppressing these arrhythmias [151]. The WPW syndrome is an abnormal route of conduction of the cardiac impulse between the atria and ventricles which predisposes to tachyarrhythmias. It should not be treated with β-blockade if it is complicated by atrial flutter and fibrillation. Conversion of atrial fibrillation to sinus rhythm by β-blockade may be seen if the precipitating cause involves a high sympathetic tone (e.g., exercise) [150], long-standing cases rarely convert to sinus rhythm [152]. Likewise atrial flutter, rarely is converted to sinus rhythm with β-blockers, but as a result of increasing the AV block a useful reduction of the heart rate can be achieved [150, 153].

Ventricular Arrhythmias. β-Blockade may be effective in ventricular premature beats which occur in ischemic heart disease, or that are induced by exercise, stress, or emotion [154]. There is the risk of heart failure, and sustained ventricular tachycardia often does not respond to β-blockers. However, paroxysmal ventricular tachycardia responds, particularly if induced by high sympathetic activity [150]. Ventricular tachycardia is a medical emergency and cardioversion should be employed, a β-blocker can sometimes be helpful [24].

Ventricular arrhythmias arising from digitalis toxicity often respond well to β-blockers, but there is a risk of fatal heart block [150]. β-Blockers are the drugs of choice in the prevention of premature ventricular beats, ventricular tachycardia, and ventricular fibrillation associated with a prolapsing mitral valve [24].

Outflow Tract Obstruction. Sufferers from the congenital heart disease known as Fallot's tetralogy may experience attacks of severe cyanosis and syncope, often precipitated by effort, crying, or stress. These episodes are associated with shut-down of the hypertrophic, right ventricular outflow tract and are thought to be the consequence of stimulation of the tract by catecholamines. This has been the rationale for the use of β-blocking drugs. The use of propranolol is probably preferable to palliative shunt surgery in buying time before corrective surgery [155].

In patients with obstruction of the outflow tract from the left ventricle, the gradient across the obstruction may appear only with sympathetic stimulation (e.g., isoprenaline infusion or exercise). Intravenous administration of β-blockers usually diminishes this gradient. Long-term use of β-blockers may abolish or diminish symptoms and may decrease sudden death [156].

Congestive Cardiomyopathy. The cause of congestive cardiomyopathy (COCM) is not known [157]. Catecholamines have toxic myocardial effects and patients with COCM may be hypersensitive to them due to downregulation of cardiac β_1-receptors. β-Blockers may diminish the effect of catecholamines: heart rate is decreased, with a decreased myocardial oxygen requirement and an up-regulation of cardiac β_1-receptors [24]. β-Blockers given initially in low dosage can benefit patients with COCM [158],

but some are precipitated into heart failure and shock.

Portal Hypertension. Cirrhosis of the liver is often the result of prolonged, excessive alcohol consumption, and leads to a rise in blood pressure in the portal venous system. β-Blockade reduces portal venous pressure because cardiac output falls, and possibly also β_2-blockade results in unopposed α-induced vasoconstriction in the hepatic artery. The nonselective drugs are probably more effective than β_1-selective agents [159–162], while labetalol, with α- and β-blocking properties, is ineffective [163].

Pheochromocytoma is a tumor, usually of the medulla of the adrenal gland, and it is characterized by the secretion of high levels of noradrenaline and adrenaline. Severe hypertension due to α-mediated vasoconstriction, tachycardia, and arrhythmias due to cardiac β-stimulation can thus occur. The α-blocker phenoxybenzamine is most often used for treating the hypertension. A β-blocker is often needed to counteract increased β-activity that occurs when phenoxybenzamine has been given. Such a combination provides good preparation for the removal of the tumor, diminishes hypertension and arrhythmias, and reverses hypovolemia associated with peripheral vasoconstriction [164, 165]. Labetalol, a drug that combines α- and β-blocking activity has also been employed [75]. An excessive rise in blood pressure from a β-blocker given alone can occur due to unopposed α-activity [56].

Subarachnoid Hemorrhage. The leaking of blood from cerebral vessels into the subarachnoid space is extremely stressful. It is associated with high levels of catecholamines, electrocardiogram (ECG) abnormalities, and focal myocardial necrosis. Patients with particularly high catecholamine levels have a poor prognosis. Many of the ECG abnormalities can be prevented by the administration of propranolol and prophylactic β-blockade to prevent catecholamine-induced myocardial necrosis [166, 167].

Head injury is associated with cardiovascular and metabolic signs of marked sympathetic overactivity. Ischemia and arrhythmias occur. Atenolol (intravenously then orally) decreases the incidence of supraventricular arrhythmias and prevents catecholamine-induced myocardial necrosis [168].

Anxiety. Patients who suffer from anxiety may experience cardiovascular symptoms such as palpitations, excessive effort dyspnoea, fatigue, precordial discomfort, tremor, and sweating. The symptoms are similar to those of sympathetic overstimulation, β-blockers are therefore used to reduce or remove the symptoms [169–171].

Migraine. Propranolol is an effective prophylactic and reduces the frequency of migraine headaches. β-Blockers with ISA do not appear as effective, while positive studies have been reported with the β_1-selective atenolol [24, 172].

Thyrotoxicosis. The part played by catecholamines in thyrotoxicosis is not clear, but many signs and symptoms are similar to adrenaline overactivity and propranolol is effective in controlling them. It is usually used prior to surgery or in the period the antithyroid drugs take to show their benefit [24].

Glaucoma. Increased intraocular pressure in untreated glaucoma leads to blindness. Many β-blockers lower intraocular pressure, but their local anesthetic effect is a disadvantage because an anesthetized cornea is injury prone. A drug without local anesthetic effects but with sufficient lipid solubility to penetrate the cornea is indicated (e.g., timolol) [24, 173, 174]. β-Blockers may be absorbed from the eye into the systemic circulation in sufficient amounts to cause adverse reactions such as asthma in susceptible patients [174]. See also → Ophthalmological Preparations, Chap. 5.2.

Other Uses of β-Blocking Drugs. β-Blockers have also been tried in several other conditions. β-Blockers, primarily propranolol, have been used in tremors, including the tremor associated with alcohol withdrawal [24].

5. Side Effects

Respiratory Side Effects. The possible precipitation of an asthma attack in susceptible subjects is the most important adverse reaction to β-blockers. The drugs significantly increase airway resistance in asthmatic subjects due to the inhibition of sympathetic tone in bronchial smooth muscle [175]. β_1-Selective blocking drugs have less effect than nonselective agents [59, 176, 177].

Although the effect is small, β-blocking drugs probably increase airway obstruction in patients with chronic obstructive lung disease [178, 179]. They also reduce the respiratory response to carbon dioxide [180].

Heart Failure. Patients with heart failure are crucially dependent on sympathetic activity to the heart to maintain cardiac output and should not normally be given a β-receptor blocking drug without prior administration of digitalis and diuretics to improve cardiac function. If these drugs alleviate the symptoms it is reasonable, with caution, then to administer to the patient a β-blocking drug. Patients who have developed heart failure while taking propranolol have been subsequently able to tolerate the drug after the administration of digoxin and a diuretic [181]. If heart failure remains uncontrolled, β-adrenergic blocking drugs should not be given. β-Blockers with ISA (alprenolol, oxprenolol, penbutolol, and pindolol) can also precipitate heart failure. A study is being undertaken to assess possible benefits of very small doses of a β_1-selective agent (bisoprolol) in heart failure [24].

It had been thought that patients receiving β-blocking drugs might be at special risk of developing acute heart failure if they sustained an intercurrent myocardial infarction. Controlled trials of intravenous, followed by oral administration of propranolol or atenolol show that this is not the case [182, 183]. Prophylactic use in high-risk patients following myocardial infarction does not increase the incidence of heart failure [184, 185]. Larger-scale trials in hypertension have not shown an increased incidence of heart failure [186, 187].

Peripheral Circulation. β-Adrenergic blocking drugs often cause cold extremities [186] as a result of peripheral vasoconstriction due to reduced cardiac output and peripheral β-blockade. There is some evidence that β_1-selective drugs give a lower incidence of cold extremities [188], but can cause a reduction in peripheral flow [189] and the exceptional case of gangrene [190]. This is also the case with nonselective drugs and those with some partial agonist activity [191].

CNS. Sleep disturbances, insomnia, increased dreaming, and tiredness are not uncommon, and there have been reports of hallucinations, depression, delirium, headache, and dystonic reactions [184, 192]. Large-scale studies have not confirmed an increased frequency of depression [184, 186]. Dreams are more frequent with the lipid-soluble drugs [193, 194]. There is some evidence that lipid-insoluble β-blocking drugs (e.g., atenolol [193, 195] or sotalol [196]) produce fewer CNS side effects.

Fatigue. Mechanisms that might explain fatigue caused by β-blocking drugs [197, 198] include reduction of exercise cardiac output, depressed release of lactic acid from muscle, a reduced blood glucose level on exercise, or interference with β_2-mediated cellular sodium efflux and potassium influx [199]. Some observations suggest that β_1-selective drugs (atenolol) interfere less with exercise than nonselective ones (propranolol) [200].

Gastrointestinal Side-Effects. Indigestion with β-blockers often with nausea [186], is not uncommon and can be avoided by taking the drug with meals. An 11 % incidence of gastrointestinal side-effects was found in a survey of 23 published studies on propanolol [192].

Sensitivity Reactions. Practolol was associated with severe sensitivity reactions which only became apparent after it had been generally released, it was then withdrawn [24]. The only other β-blocker that may be associated with a high incidence of positive antinuclear antibodies appears to be acebutolol [201, 202]. The oculomucocutaneous syndrome is rare [198, 203].

Skin reactions, most often psoriasiform or lichenoid, are associated with β-blocking drugs [186, 198]. Retroperitoneal fibrosis has been reported in patients taking β-blocking drugs, but this is thought to be coincidental rather than

causative [198, 204]. Sclerosing peritonitis has been associated with practolol, but probably does not occur with other β-blockers [205].

Withdrawal of β-Blocking Drugs. There is a period of β-receptor hypersensitivity after withdrawal of β-blocking drugs without ISA. This is important in patients with ischemic heart disease and may be associated with an increased incidence of ischemic events. It is of less importance in uncomplicated hypertensive patients, but gradual reduction of dosage is recommended [206]. The occurrence of important adverse reactions to β-adrenergic blocking drugs is relatively uncommon, particularly if cases of heat failure and asthma are avoided. Severe adverse cardiac reactions may occur soon ofter the start of treatment, even with small doses; but once therapy is introduced, a gradual increase in dosage is not likely to precipate adverse reactions.

6. Individual β-Blocking Drugs

More detailed accounts of individual β-adrenoceptor blocking drugs can be found [24, 207]; their chemistry is summarized in [208] and their structure – activity relationship discussed in [209]. The principal β-blocking drugs that have been marketed are described, many other examples have been reported.

Acebutolol (hydrochloride) [*37517-30-9*], 1-(2-acetyl-4-*n*-butyramidophenoxy)-2-hydroxy-3-isopropylaminopropane, β_1-selective, some partial agonist activity (P.A.A.), [210–213]. $C_{18}H_{29}ClN_2O_4$, M_r 372.9, crystals *mp* 141 – 143 °C, octanol – water partition coefficient 0.68.

Trade Names. M & B 17 803 A, Sectral, Diasectral, Neptall, Prent.

Pharmacodynamics. Acebutolol is a competitive antagonist at β-receptors, it is selective for the β_1-receptor with less effect at the β_2-receptor. It has some partial agonist activity.

Pharmacokinetics. Acebutolol is fairly well absorbed (> 50 %) with considerable presystemic metabolism; the systemic bioavailability is 50 – 70 %. The peak concentration is reached 2 – 3 h after oral administration, the half-life is 5 – 9 h. Acebutolol is metabolized to diacetolol which is also a β-blocking agent, about 3 – 25 % is excreted unchanged. Acebutolol has a volume of distribution of about 1.2 L/kg, which indicates some accumulation in the tissues.

Uses. Acebutolol has been promoted for the treatment of hypertension, angina pectoris, and in certain cardiac arrhythmias.

Atenolol [*29122-68-7*], 1-*p*-carbamoylmethylphenoxy-3-isopropylamino-2-propanol, β_1-selective, [214–217]. $C_{14}H_{22}N_2O_3$, M_r 266.35, crystals from ethyl acetate *mp* 146 – 148 °C, octanol – water partition coefficient 0.015.

Trade Names. ICI 66 082, Tenormin, Atenolol, AteHexal, Ibinolo, Myocard, Prenormine, Seles Beta, Selobloc, Tenoblock, Tenormin, Uniblock, Uniloc.

Pharmacodynamics. Atenolol is a competitive antagonist at the β_1-receptors but its action at β_2-receptors is very weak. It is without partial agonist activity.

Pharmacokinetics. As with other hydrophilic drugs, oral absorption of atenolol is poor (ca. 44 %). There is no significant hepatic metabolism. The peak plasma concentration occurs 2 – 4 h after an oral dose, plasma half-life is 6 – 8 h. Most is excreted unchanged in the urine. The volume of distribution is low (0.7 L/kg) as atenolol has a low lipid solubility; it is the most hydrophilic β-blocking drug that is generally available.

Uses. Atenolol has been promoted for the treatment of hypertension, angina pectoris, in cardiac arrhythmias, and myocardial infarction.

Betaxolol (hydrochloride)[*63659-19-8*],(±)-1-(isopropylamino)-3-[*p*-(cyclopropylmethoxyethyl)phenoxy]-2-propanol, β_1-selective, [218, 221]. $C_{18}H_{30}ClNO_3$, M_r 343.9, crystals *mp* 116 °C.

Trade Names. SLD 212 SL-75 212 Kerlone, Betoptic, Betoptima.

Pharmacodynamics. Betaxolol is relatively β_1-selective, a competitive antagonist with weak membrane-stabilizing action, and no partial agonist activity at low doses, although there may be some at high doses.

Pharmacokinetics. Betaxolol is well absorbed, bioavailability is 80 – 90 % and, although lipid solubility is high, first-pass metabolism is minimal. Peak concentration is achieved 2 – 4 h after oral administration, plasma half-life is 13 – 24 h, the volume of distribution is about 6.1 L/kg. Metabolism is slow, ca. 10 – 15 % is excreted unchanged.

Uses. It has been promoted for the treatment of hypertension and angina, and as eye drops for glaucoma.

Bisoprolol (hemifumarate) [*66722-44-9*], (±) -1-[[α-(2-isopropoxyethoxy)-*p*-tolyl]oxy]-3-(isopropylamino)-2-propanol, β_1-selective, [70, 222–226]. $C_{18}N_{31}NO_4$, M_r (free base) 325.45, bisoprolol hemifumarate: $C_{36}H_{64}N_2O_{12}$, crystals *mp* 100 °C, octanol – water partition coefficient 4.8.8

Trade Names. EMD 33.512, Bisobloc, Concor, Emconcor, Emcor, Pacteus, Detensiel, Euradel, Isoten, Maintate, Monocor, Soprol.

Pharmacodynamics. Bisoprolol is a highly selective β_1-receptor antagonist. It has no partial agonist activity, and no membrane activity within the therapeutic range.

Pharmacokinetics. Bisoprolol is well absorbed (> 90 %). Peak concentration is reached in 3 h. The plasma half-life is relatively long (ca. 10 – 12 h). It is modestly lipophilic with an apparent volume of distribution of 3 L/kg. About 30 % of the plasma concentration is bound to protein. About 50 % of bisoprolol is metabolized in the liver, 50 % is excreted unchanged.

Uses. Bisoprolol has been promoted for the treatment hypertension, angina pectoris, and some cardiac arrhythmias, it is also used in the management of hyperthyroidism.

Carteolol (hydrochloride) [*51781-21-6*], 5-[3-(*tert*-butylamino)-2-hydroxypropoxy]-3,4-dihydrocarbostyril, [227–231]. Low selective β-blockade, with partial agonist activity, $C_{16}H_{24}N_2O_3HCl$, M_r 328.8, *mp* 278 °C, octanol – water partition coefficient 0.21.

Trade Names. Abbott 43 326, OPC 1085 Arteolol, Arteoptic, Caltridren, Carteol, Cartrol, Endak, Mikelan, Ocupress, Tenalet, Tenalin, Teoptic.

Pharmacodynamics. Carteolol is a competitive antagonist at both the β_1- and β_2-receptors with some partial agonist action. It has a weak membrane-stabilizing (local anesthetic) action.

Pharmacokinetics. Carteolol is well absorbed (ca. 95 %). There is some presystemic (first pass) hepatic metabolism (ca. 15 %) so that systemic bioavailability exceeds 80 %. The peak plasma concentration is reached in about 1.5 h, the plasma half-life averages 5.8 h. Carteolol is excreted mainly unchanged, a small amount is metabolized by the liver. Plasma protein binding is about 15 %, the volume of distribution is about 4 L/kg.

Uses. Carteolol has been used in the treatment of hypertension, angina pectoris, arrhythmias, and in cardiac neurosis. An ocular preparation is available for the treatment of glaucoma.

Carvedilol [*72956-09-3*], (RS)-1-(9*H*-carbazol-4-yloxy)-3-[[2-(2-methoxyphenoxy)ethyl] amino]-2-propanol, nonselective β-blockade, α-receptor blockade, [232–234]. $C_{24}H_{26}N_2O_4$, M_r 406.5, *mp* 114 – 115 °C, octanol – water partition coefficient 3.3.

Trade Names. BM 141 90, DQ 2466, Kredex, Dilatrend.

Pharmacodynamics. Carvedilol has a nonselective β-adrenoceptor blocking activity for both β_1- and β_2-receptors. It additionally has a vasodilator activity which seems to be dependent on an α_1-receptor blocking action, it thus inhibits the vasoconstrictor action of adrenaline and noradrenaline in vascular smooth muscle. The vasodilator action results in a reduced peripheral resistance, and represents an additional mode of action for lowering blood pressure.

Pharmacokinetics. Carvedilol is well absorbed (ca. 80 %) but with extensive presystemic first-pass metabolism by the liver. Systemic bioavailability is therefore low (ca. 23 %). The peak plasma concentration is reached 1 – 2 h after the dose. The plasma half-life averages 6.4 h. Carvedilol is eliminated by liver metabolism. Over 95 % is bound to plasma proteins, its volume of distribution is 2.0 L/kg.

Uses. Carvedilol is promoted for the treatment hypertension. Its value in other conditions (e.g., angina) is still being evaluated.

Celiprolol [*56980-93-9*], *N*-[3-acetyl-4-(3′-*tert*-butylamino-2′-hydroxy)propoxy]phenyl-*N*′-diethylurea, β_1-selective, P.A.A., [235–237]. $C_{20}H_{33}N_3O_4$, M_r 379.5, *mp* 110 – 112 °C.

Trade Names. Celectol, Selectol.

Pharmacodynamics. Celiprolol is a competitive β_1-receptor antagonist. It has partial agonist activity which is mediated via β_2-receptors. It has some weak α_2-blocking action but this may not be clinically important.

Pharmacokinetics. Absorption of celiprolol is only about 20 %. Peak levels are reached 2 – 3 h after an oral dose, the plasma half-life is 4 – 5 h. Very little is metabolized, it is almost all excreted unchanged. The volume of distribution is low, celiprolol is markedly hydrophilic.

Uses. Celiprolol has been promoted for the treatment hypertension and angina pectoris.

Labetalol (hydrochloride) [*32780-64-6*], 5-[1-hydroxy-2-[(1-methyl-3-phenylpropyl)amino] ethyl]salicylamide hydrochloride, nonselective β-blockade, some partial agonist action, α-receptor blockade, [75, 238–240]. $C_{19}H_{24}N_2O_3$-HCl, M_r 364.9 (free base 328.4), *mp* 187 – 189 °C, octanol – water partition coefficient 7.08.

Trade Names. AH 5158, SCH 15 719 W, Amipress, Ibidomide hydrochloride, Ipolab, Labelol, Labrocol, Normadate, Normodyne, Presdate, Pressalolo, Trandate.

Pharmacodynamics. Labetalol is a competitive, nonselective β-antagonist, it blocks both β_1- and β_2-receptors with some β_2-agonist effect. Labetalol also has some α_1 (postsynaptic) blocking activity and thus inhibits the constrictor effect of adrenaline and noradrenaline on vascular smooth muscle. This reduces peripheral resistance, representing an additional mode of action to help lower the blood pressure.

Pharmacokinetics. Labetalol is rapidly absorbed but undergoes variable extensive presystemic metabolism. The systemic bioavailability lies between 11 and 86 %. The peak plasma concentration is reached in 40 min to 1.5 h. The plasma half-life averages 3.3 h. Labetalol is almost entirely metabolized by the liver, < 5 % is excreted unchanged in the urine. The plasma protein binding is ca. 50 %, the volume of distribution varies between 3.4 and 10.7 L/kg.

Uses. Labetalol is used for the treatment of hypertension, angina in patients with hypertension, and in pheochromocytoma.

Metoprolol (tartrate), [*56392-17-7*], (±)-1-(isopropylamino)-3-[*p*-(β-methoxyethyl)phenoxy]-2-propanol, β_1-selective, [241–245]. $C_{34}H_{56}N_2$-O_{12}, M_r 684.8 (free base 267.38), octanol – water partition coefficient 0.5.

Trade Names. CGP 2175, H.93/26, Beloc, Betaloc, Betaloc SA, Lopressor, Lopresor, Lopresor S.R., Metoros, Prelis, Seloken, Selopral.

Pharmacodynamics. Metoprolol is a competitive antagonist at β_1-receptors without partial agonist activity. It has membrane-stabilizing activity, but only at concentrations higher than those achieved clinically.

Pharmacokinetics. Metoprolol is well absorbed but undergoes extensive, variable, presystemic metabolism in the liver. Systemic bioavailability ranges between $< 5\,\%$ to $> 50\,\%$. The peak concentration is reached in 2 – 3 h, the plasma half-life is ca. 4 h. Most metoprolol is metabolized by the liver, only 10 % is excreted unchanged. About 12 % is bound to plasma protein. Metoprolol has a large volume of distribution (ca. 3 – 6 L/kg).

Uses. Metoprolol has been widely promoted for the treatment of hypertension, angina pectoris, early intervention and long-term use after myocardial infarction, arrhythmias, in the prophylaxis of migraine, and in the management of thyrotoxicosis.

Nadolol [*42200-33-9*], 1-(*tert*-butylamino)-3-[(5,6,7,8-tetrahydro- *cis*-6,7-dihydroxy-1-naphthyl)oxy]-2-propanol, nonselective, SQ 11 725, [246–249]. $C_{17}H_{27}NO_4$, M_r 309.42, *mp* 124 –136 °C, octanol – water partition coefficient 0.066.

Trade Names. Anabet, Cogard, Solgol.

Pharmacodynamics. Nadolol is a nonselective competitive β-receptor antagonist (i.e., it blocks both the β_1- and β_2-receptors). It does not possess partial agonist or membrane-stabilizing activity.

Phamacokinetics. Nadolol is poorly absorbed (ca. 30 %). There is no presystemic metabolism so that the bioavailability of 30 % is the same as the proportion absorbed. Absorption varies between individuals. The peak concentration occurs 1 – 4 h after oral administration, the plasma half-life is 17 – 24 h. Nadolol is not metabolized, and is excreted in the urine unchanged. It therefore accumulates in patients with renal failure. Nadolol is hydrophilic, about 30 % is bound to plasma proteins. It has a widely varying volume of distribution (ca. 2 L/kg).

Uses. Nadolol has been promoted for the treatment of hypertension, angina pectoris, for migraine prophylaxis, and relief of hyperthyroid symptoms.

Oxprenolol (hydrochloride), [*6452-73-9*], 1-(isopropylamino)-2-hydroxy-3-[*o*-(allyloxy)phenoxy]propane, nonselective, some partial agonist activity, [250–253]. $C_{15}H_{23}NO_3HCl$, M_r 301.8 (free base 265.3), *mp* 107 – 109 °C, octanol – water partition coefficient 1.6.

Trade Names. Ba 39 089, Apsolox, Laracor, Paritane, Slow-Pren, Slow-Trasicor, Trasicor, Tracosal, Trasacor.

Pharmacodynamics. Oxprenolol is a nonselective competitive β-receptor antagonist (i.e., it blocks both β_1- and β_2-receptors). It has some partial agonist activity, but less than that of pindolol. Its membrane-stabilizing activity is probably not of clinical significance.

Pharmacokinetics. Oxprenolol is well absorbed but undergoes extensive, variable, presystemic elimination by the liver (ca. 25 – 80 % of the dose). Bioavailability after oral administration is therefore variable and may be as low as 20 %. Absorption is rapid, peak concentrations being reached between 0.5 and 1.5 h, the half-life is ca. 2 h. Oxprenolol is almost entirely metabolized by the liver (ca. 95 %). It is highly bound (70 – 80 %) to plasma. The volume of distribution is 1.6 L/kg.

Uses. Oxprenolol has been promoted for the treatment of hypertension, angina pectoris, certain arrhythmias, hypertrophic obstructive cardiomyopathy, and the control of somatic manifestations of anxiety.

Pindolol [*13523-86-9*], 4-[2-hydroxy-3-(isopropylamino)-propoxy]indole, nonselective, marked partial agonist effect, [254–257].

$C_{14}H_{20}N_2O_2$, M_r 248.32, *mp* 171 – 173 °C, octanol – water partition coefficient 0.41.

Trade Names. LB 46, Betadren, Betapindolol, Blocklin L, Calvisken, Decreten, Durapindol, Glauco-Viskin, Pectobloc, Pinbetol, Pynastin, Visken.

Pharmacodynamics. Pindolol is a competitive nonselective β-receptor blocking drug (i.e., it blocks both β_1- and β_2-receptors). It has a marked partial agonist activity at the β-receptor.

Pharmacokinetics. Pindolol is completely absorbed after oral administration. There is no presystemic metabolism so that bioavailability approaches 100 %. Peak concentrations are reached 1 – 2 h after oral administration, the plasma half-life is 2.5 – 4 h. Pindolol is 40 % excreted in the urine unchanged, the remainder is metabolized in the liver. About 50 – 70 % of the blood concentration of pindolol is bound to plasma protein. The volume of distribution is 1.2 – 2.0 L/kg.

Uses. Pindolol has been promoted for the treatment of hypertension, angina, and tachyarrhythmias.

Practolol (hydrochloride), [*6673-35-4*], 1-(4-acetamidophenoxy)-3-isopropylamino-2-propanol, β_1-selective, partial agonist activity, [258–260]. $C_{14}H_{22}N_2O_3Cl$, M_r 302.8 (free base 266.34), *mp* 140 – 142 °C, octanol – water partition coefficient 0.06.

Trade Names. I.C.I. 50 172, AY 21 011, Dalzic Eraldin.

Pharmacodynamics. Practolol is a competitive β_1-selective blocking drug. It has strong partial agonist activity at the β_1-receptor. It is no longer used for oral treatment because of severe oculomucocutaneous reactions which may induce irreversible damage of the eyes, fibrotic pleural and peritoneal reactions, and a psoriasiform skin rash.

Pharmacokinetics. Practolol is well absorbed orally, with negligible presystemic metabolism. Bioavailability is >95 %. Peak blood levels are reached 1 – 3 h after oral administration. The half-life is ca. 11.5 h. Practolol is almost entirely excreted unchanged in the urine. Plasma protein binding is negligible. The volume of distribution is 1.6 L/kg.

Uses. Practolol was previously used for hypertension and angina pectoris but this usage was stopped because of the oculomucocutaneous syndrome. The intravenous use for the control of tachyarrhythmia was continued for many years, but this preparation has now also been withdrawn.

Propranolol (hydrochloride), [*318-98-9*], 1-(isopropylamino)-3-(1-naphthyloxy)-2-propanol, nonselective, no partial agonist activity, [261–264]. $C_{16}H_{21}NO_2HCl$, M_r 295.8 (free base 259.3), *mp* 163 – 164 °C, octanol – water partition coefficient 3.65.

Trade Names. ICI 45 520, AY 64 063, NSC-91 523, Angilol, Beprane, Beta-Tablinen, Caridorol, Dumopranol, Elbrol, Inderex, Kemi, Propahexal, Pylapron, Sloprolol.

Pharmacodynamics. Propranolol is a nonselective β-adrenoceptor blocking drug (i.e., it blocks both β_1- and β_2-receptors). It has no partial agonist activity. It has membrane-stabilizing activity at concentrations which are, however, only rarely achieved with high dosage.

Pharmacokinetics. Propranolol is completely absorbed after oral administration, but because of variable, extensive, first-pass metabolism in the liver bioavailability tends to be low (5 –50 %). There is thus considerable variation in plasma concentration between individuals. Peak concentrations occur 1 – 2 h after oral administration, the plasma half-life is 3.9 h. Propranolol is almost entirely metabolized in the liver, only 1 – 4 % is excreted unchanged in the urine and feces. It is highly bound (80 – 95 %)

to plasma protein. The volume of distribution is high (ca. 3 L/kg).

Uses. Propranolol has been widely evaluated, most of the pioneer work on β-blocking drugs was performed with this drug. It has been promoted for the treatment hypertension, angina pectoris, secondary prevention after myocardial infarction, certain cardiac arrhythmias, catecholamine excess in pheochromocytoma (in combination with α-receptor blockade), somatic manifestations of anxiety, in the management of thyrotoxicosis, tremor of the limbs, migraine prophylaxis, hypertrophic obstructive cardiomyopathy, and to reduce the risk of gastrointestinal hemorrhage in portal hypertension.

Sotalol (hydrochloride), [*959-24-0*], 4′-[1-hydroxy-2-(isopropylamino)ethyl]methanesulfonamide, nonselective, no partial agonist activity, [265,266]. $C_{12}H_{20}N_2O_3SHCl$, M_r 308.8 (free base 272.4), *mp* 207 °C, octanol – water partition coefficient 0.79.

Trade Names. MJ-1999, Beta Cardone, Betapace, Sotacor, Sotalex.

Pharmacodynamics. Sotalol is a nonselective competitive β-adrenergic blocking drug, without partial agonist activity and membrane-stabilizing (local anesthetic) activity. Its β-blocking activity is associated with the L-isomer, but both the D- and L-isomers possess extra antiarrhythmic properties. Sotalol prolongs the duration of the action potential of heart muscle (the so- called Class III effect).

Pharmacokinetics. Sotalol is well absorbed and first-pass metabolism is negligible, bioavailability is therefore 100 %. The peak plasma concentration is reached in 2 – 3 h, the plasma half-life ranges between 7 and 18 h. Sotalol is not metabolized, and is mostly excreted unchanged by the kidney. Plasma protein binding is negligible. The volume of distribution is 1 – 2 L/kg.

Uses. Sotalol is promoted for the treatment of angina pectoris, hypertension, cardiac arrhythmias, the reduction of the recurrence of myocardial infarction, and in the management of thyrotoxicosis.

Timolol (hydrogen maleate), [*26921-17-5*], *S*-(−)-3-(3-*tert*-butylamino-2-hydroxypropoxy)-4-morpholino-1,2,5-thiadiazole, nonselective, no partial agonist activity, [267–270].

$C_{17}H_{28}N_4O_7S$ (hydrogen maleate salt), M_r 432.5 (free base 316.4), *mp* 202 °C, octanol – water partition coefficient 1.16.

Trade Names. MK 950, Timolol maleate Betim, Blocadren, Proflax, Timacor, Timolate, Timoptic, Timoptol, Timotre, Tenserin.

Pharmacodynamics. Timolol is a competitive antagonist at both β_1- and β_2-receptors. It is without significant partial agonist activity, and has no local anesthetic effect.

Pharmacokinetics. Timolol is almost completely absorbed, but there is considerable first-pass metabolism (50 – 79 %) in the liver, although not as much as with propranolol. Bioavailability is 30 – 50 %. There is a 2 – 7-fold variation in blood levels. The peak concentration occurs 1 – 2 h after oral administration, half is metabolized in the liver but 20 % is excreted unchanged in the urine. Timolol is bound to plasma protein, binding of 10 – 80 % has been reported. The volume of distribution is large (1.74 – 3.64 L/kg).

Uses. Timolol has been promoted for the treatment of hypertension, angina pectoris, migraine prophylaxis, the reduction in the recurrence of myocardial infarction, and as eye drops (Timoptol) in the treatment of glaucoma.

1. Introduction

The term *reduction* generally denotes a chemical process in which one reactant – the oxidizing agent – accepts electrons. This process can only take place if an electron donor, namely, the reducing agent, is also present; that is, oxidation (donation of electrons) and reduction (acceptance of electrons) always occur in tandem (redox reaction). During reduction a reducing agent is converted into its corresponding oxidizing agent, and vice versa, i.e., the (arbitrary) designation of a redox process as reduction depends exclusively on the synthetic objective.

Historically, reductions – particularly those involved in the extraction of metals from ores – are among the oldest industrial processes, with far-reaching cultural and historical significance (Iron Age, Bronze Age). In addition to the winning of metals from their salts and oxides by means of carbon, carbon monoxide, petroleum, natural gas, electrochemical reduction, inorganic reductants, or hydrogenation, reduction also plays a significant role in the production of low-valence basic chemicals, such as ammonia, silicon and phosphorus compounds, (complex) metal hydrides and carbonyls, hydrogen, and organometallic compounds.

In organic chemistry any change in a functional group is termed reduction if it involves a decrease in oxidation state. The corresponding electron acceptance can proceed by reaction with hydrogen or other electropositive atoms or compounds, as well as elimination of oxygen or other electronegative elements or groups.

If various reducing agents are arranged in the order of their electron-donor properties the so- called electrochemical series is obtained, in which the standard redox potentials provide a measure of the "reductive power" – the electromotive force – of substances relative to a standard hydrogen electrode. The reductive power increases with decreasing standard potential [1–3]. These well-documented numerical values enable predictions to be made of the course and equilibrium position of a reduction, but only in the case of purely thermodynamically controlled reactions (i.e., normally involving inorganic compounds and metals). In organic chemistry, questions of reaction kinetics, selectivity, regiospecificity, and stereospecificity, as well as reaction conditions, are often the subject of detailed experimental investigations.

2. Reduction of Individual Classes of Substances

Among reduction methods, catalytic hydrogenation is extremely important because of its universal applicability [4]; most of the processes

[a] + Reduction possible; − reduction not possible.
[b] Reduction to aldehyde.
[c] In some cases reduction takes place only as far as azo compound.

discussed in the following sections can be carried out successfully by catalytic hydrogenation (→ Hydrogenation and Dehydrogenation). Hydrogenation is of further importance due to the rapid development of optically active catalysts, which offer the possibility of carrying out enantioselective syntheses [5–7].

A complete description of all reduction processes and reducing agents is impossible within the scope of this article, given the wealth of material available. The topic of reduction is however discussed in great detail, in both general and selected aspects, in numerous monographs and reviews [8–13]. This article describes the classes of reductive compounds (see Table 1) and deals with various reducing agents.

3. Electrolysis

The importance of electrochemical reduction methods derives from the fact that some reducing agents can be obtained only by means of cathodic reduction. These include, in particular, strongly electropositive metals such as lithium, sodium, potassium, magnesium, calcium, or aluminum [2]. Other reducing agents are often far more expensive or are associated with environmental hazards. Detailed theoretical and experimental information on electrolysis can be found in [3], [70], [188] (see also → Electrochemistry).

3.1. Inorganic Processes

Electrometallurgy occupies a dominant role among the applications of electrolytic reduction processes; either aqueous solutions or melts (electrothermic processes) are used. A distinction can be made between actual winning of a metal (extractive electrolysis) and its subsequent purification (electrolytic refining). In electrolytic refining, impure metals are reoxidized at the anode and migrate as metal ions to the cathode for reductive deposition (electrolytic copper, nickel, silver, and zinc). Electrolytic degreasing is another reductive purification process in which grease is removed by the formation of hydrogen at surface of a metal acting as a cathode and is subsequently saponified in the basic solvent.

Table 1. Commonly used reducing agents for individual compound classes

Compound class	Target product	Reducing agent	Example	Yield, %
1. Hydrocarbons				
Cycloalkane	alkane	Li/NH_3 [14], $Zn/ZnCl_2$ [15]		
Alkene	alkane	Na [16], N_2H_2 [17], borane [18]		91
	borane	borane [18]		98
Alkyne	alkene	$LiAlH_4$ [19], MgH_2 [20], borane [18]		91
	alkane	$LaNi_5H_6$ [21], $KO_2CN{=}NCO_2K$ [22], $LiAlH_4$ [19]	$PhC{\equiv}CC{\equiv}CPh \xrightarrow[THF/MeOH,\ 25\,°C,\ 1\,h]{LaNi_5H_6} Ph(CH_2)_4Ph$	97
Aromatic hydrocarbon	cyclic olefin	Na/NH_3, Li/NH_3 [23], electrolysis [24]		83
2. Halogenated compounds				
Alkyl halide	alkane	$LiEt_3BH$ [25], $LiAlH_4/FeCl_3$ [26]	$H_3C{-}(CH_2)_7{-}Cl \xrightarrow[THF,\ 25\,°C]{LiEt_3BH} H_3C{-}(CH_2)_6{-}CH_3$	91
Dihalide	olefin	Zn [27], Fe–graphite [28]		91
Aryl halide	aryl	NaH_2PO_2 [29], i-$C_3H_7OH/h\nu$ [30], $Et_3SiH/Pd/C/h\nu$ [31], $LiAlH_4$ [32]		91
	biaryl	Cu [33]		96

Table 1. (Continued)

Compound class	Target product	Reducing agent	Example	Yield, %
3. Oxygen-containing compounds				
Alcohol	alkane	HI/HOAc [34], SmI_2/Ac_2O [35]		85
Phenol	aromatic hydrocarbon	Li, Na, or K/NH_3 [36], electrolysis [37]		77
	cyclohexanol (cyclohexanone)	electrolysis [38]		41 (**1**), 50 (**2**)
Peroxide	alcohol	$LiAlH_4$ [39], $NaBH_4$ [40], Na_2SO_3 [41]	$R-O-OH \xrightarrow[H_2O,\ 20\,°C]{NaBH_4} ROH$	
Ozonide	alcohol aldehyde	$BH_3 \cdot S(CH_3)_2$ [42], $LiAlH_4$ [39] $NaBH_4$ [40]	$H_3C-(CH_2)_7-CH=CH_2 \xrightarrow[CH_2Cl_2,\ \text{reflux, 1 h}]{1)\ O_3;\ 2)\ BH_3 \cdot S(CH_3)_2} H_3C-(CH_2)_8-OH$	100
Ether	hydrocarbon	K [43], $LiEt_3BH/Pd(PPh_3)_4$ [44]		85
Epoxide	alcohol	$LiAlH_4$ [45], NaH [46]		62
	alkene	P_2I_4 [47], $Co_2(CO)_8$ [48]	$C_7H_{15}-\triangle O \xrightarrow[CH_2Cl_2,\ \text{reflux, 3 h}]{P_2I_4} C_7H_{15}-\!\!\!

Table 1. (Continued)

Compound class	Target product	Reducing agent	Example	Yield, %
	hydrocarbon	$(PhCO_2)_2BH$ [56], Zn–Hg [57], $BH_3 \cdot THF$ [58]	$H_3C-(CH_2)_8-CHO \xrightarrow[CHCl_3,\ 0\,°C,\ 1\,h]{1)\ TosNHNH_2;\ 2)\ (PhCO_2)_2BH} H_3C-(CH_2)_8-CH_3$	91
	amine	HCO_2H/amine [59], [60]		85
	olefin	$TiCl_3$/Zn [61]		65
Ketone	alcohol	$LiAlH_4$ [62], Li, Na, K, Cs, Ca, Sr, or Ba [63], baker's yeast [51]		93
	pinacol	electrolysis [64], $TiCl_4$/Zn [53]	$Ph_2CO \xrightarrow[Hg\ cathode,\ CrCl_3]{+\,2e^- + 2H^+} HO-(Ph)_2-(Ph)_2-OH$	70
	amine olefin	HCO_2H/amine [59], [60], [65] $TiCl_4$/Zn [66]		86
	hydrocarbon	N_2H_4 [67], HI/P [68], Zn/Hg [69]		
Sugar	polyol	electrolysis [70], $LiAlH_4$ [71]	$HO-CH_2(CHOH)_4-CHO \xrightarrow[Pb\ cathode,\ 20-30\,°C]{+\,2e^- + 2H^+} HOCH_2-(CHOH)_4-CH_2OH$	
	aldose	$NaBH_4$ [71]		
	ketose	Zn [72]	$HO-CH_2-(CH-OH)_3-CO-CHO \xrightarrow[80-90\,°C,\ 1\,h]{Zn/CH_3COOH} HO-CH_2-(CH-OH)_3-CO-CH_2-OH$	

Table 1. (Continued)

Compound class	Target product	Reducing agent	Example	Yield, %
Quinone	hydroquinone	Zn [73], $Na_2S_2O_4$ [74], electrolysis [75], $SnCl_2$ [76]		95
	hydrocarbon	HI [77], Zn/pyridine/AcOH [78]		89

Extractive electrolysis is the most important process for producing the strongly electropositive metals of groups 1 – 3 of the periodic table. Metals produced electrothermally include, for example, lithium from LiCl – KCl mixtures, sodium from NaOH or NaCl – $CaCl_2$, magnesium from $MgCl_2$– $CaCl_2$, and aluminum from cryolite melts [2]. In addition, cobalt, cadmium, niobium, and tantalum, among others, are also obtained electrochemically. Hydrogen, which is itself employed as a universal reducing agent, is formed in the industrial production of caustic soda by chlor-alkali electrolysis.

3.2. Organic Processes

Whereas, by definition, oxidative processes such as the dimerization of radical cations or their combination with nucleophilic species, as well as solvolysis, elimination, or rearrangement of carbenium ions, occur at the anode (i.e., the electron acceptor), reactions at the cathode (i.e., the electron donor), involve reductive processes. The great advantage of the cathode as reducing agent is that its potential can be adjusted to any given value, which permits more selective reduction (and also anodic oxidation) than purely chemical methods. Electrical power is normally cheaper than chemicals and greatly reduces pollution. The disadvantages of electrolysis, particularly with organic processes, include possible secondary reactions with the solvent, whose choice is restricted by criteria such as temperature, polarity, and conductivity, as well as the need for special equipment and detailed technical knowledge.

Electrolytic syntheses were first evaluated in detail a hundred years after the discovery of oxidative Kolbe electrolysis [189], [190]. Cathodic reduction was tested for the first time industrially in the hydrodimerizing adiponitrile synthesis [191], [192]. In addition to its use in refunctionalization reactions, such as cathodic hydrogenation, cleavage, and elimination, electrochemical reduction at the cathode is also used for C – C bond formation as a consequence of a reductive umpolung, or for radical pinacol couplings [193]. The removal of protective groups by cathodic cleavage and elimination proceeds smoothly, as does cathodic dehalogenation, reductive carboxylation of aryl halides, or the enantiospecific reduction of appropriate prochiral ketones [193]. The latter reduction proceeds via the two electron mediators methyl viologen and nicotinamide adenine dinucleotide (NADH) from yeast cells, whose reduction equivalents are regenerated continuously at the cathode.

The most important electrochemical process, namely, the hydrodimerizing production of adipic acid dinitrile – with an output of 250 000 t/a – was improved continuously from 1961 to the early 1980s with regard to both space – time yield and economy.

Another industrial process is the reduction of *o*-nitrophenol to the corresponding amine [194]. In addition to these processes, electrochemical reduction plays an important role in the synthesis of valuable, expensive, or otherwise difficultly accessible products in fairly small to moderate amounts.

Electrochemical reactions in the presence of D_2O or T_2O lead to incorporation of deuterium or tritium in appropriate substrates [195], [196].

A detailed review of synthetic aspects of organic electrochemistry can be found in [197]

4. Individual Reducing Agents

The importance of individual reducing agents varies greatly, depending on their respective areas of application. Catalytic processes such as hydrogenation, hydrogenolysis, hydroformylation, reductive amination, or reductive alkylation predominate in large-scale industrial syntheses. The economic, and above all, ecological advantages in the use of hydrogen as an inexpensive reducing agent will become even more important in the future because of increasingly serious environmental problems. The selectivity of catalytic hydrogenation can be extremely fine-tuned by the choice of catalyst metal, carrier, solvent, pressure, and temperature [198]. Developments in the field of asymmetrical catalysis also support this trend [6], [7]. In particular, the latter is consistent with increasingly stringent requirements for the stereochemical uniformity of chemical products,especially pharmaceuticals.

In laboratory chemistry, on the other hand, noncatalytic reduction processes with highly specific and, in some cases, very expensive reactants play an important role. In this case, attention is concentrated on a more product-oriented

approach, and the problem of effluent and waste material is to some extend ignored. Because of the small batch sizes, economic and ecological considerations are not given the fundamental importance that is their due industrially, although here too a gradual change can be foreseen.

Finally, enzymatic processes and thus enzyme-catalyzed reductions have in recent years become much more important in technology as well as in the laboratory. There are many reasons for the major advances in enzymatic reduction. Common objections against the use of enzymes – for example, their restriction to aqueous media, the narrow substrate or product specificity, or lack of thermal stability – have been overcome. Furthermore enzymatic reductions often lead to a substantial simplification of process control, enable synthetic routes to be shortened, or improve regioselectivity or stereoselectivity. The main advantages of biocatalytic process control are the milder (energy- and material-conserving) reaction conditions, extremely high stereoselectivities with a much wider range of substrates, and growing number of commercially available enzymes.

4.1. Coal, Petroleum, Natural Gas

The economic importance of fossil fuels in industrialized countries is associated predominantly with their role as sources of energy. In internal combustion engines and heating systems they represent the reducing agents of choice for the ubiquitous oxygen, although unfortunately only the useful energy of this redox reaction is of interest. Depending on the location and process, various fossil fuels are often interchangeable; however, the area of application of natural gas is expanding for ecological reasons. Coal is an important reducing agent for the production of many metals and nonmetals, such as lead, chromium, nickel, titanium, phosphorus, and hydrogen, as well as carbon monoxide. Generator gas, produced from coal in special furnaces (generators), is a powerful reducing agent:

$$2\,C + \text{air} \longrightarrow 2\,CO + 4\,N_2$$

In the unconsumed part of the heated coke layer, CO and CO_2 are in a strongly temperature- and concentration-dependent redox equilibrium (Boudouard equilibrium), which plays an important part in all industrial processes involving the reduction of oxygen compounds with excess coal. At the temperature prevailing in the blast furnace process a gas mixture termed furnace gas is thus formed.

Carbon monoxide also acts as a reductant in the synthesis of metal carbonyls from metal salts or elemental metals, and opens up a pathway to a large number of valuable organometallic compounds [95], [199]. The carbonyl processes for refining nickel are examples of industrial purification processes involving metal carbonyls (see → Nickel, Chap. 6.3., → Nickel, Chap. 6.4.).

4.2. Hydrogen

About, 77 % of all hydrogen is obtained from petroleum – natural gas, 18 % from coal, and only ca. 4 % electrolytically [200]. Hydrogen is used principally as a chemical raw material, for example, in the synthesis of ammonia and methanol, and in metallurgy. Hydrogen reduces oxides or halides and is used to obtain metals such as tungsten, molybdenum, cobalt, and iron in pure form. Mixtures of CO and H_2 are starting materials for Fischer – Tropsch reactions (C_1 chemistry)

$$x\,CO + y\,H_2 \xrightarrow{\text{catalyst}} \text{CHO products}$$

which can be used together with cheap coal for the synthesis of gasoline and diesel fuel (SASOL Plant, South Africa; see → Coal Liquefaction, Chap. 2.2.6., [201]). Synthesis gas can be obtained by the controlled combustion of petroleum, by reforming natural gas

$$CH_4 + H_2O \rightleftarrows CO + 3\,H_2$$

or by coal gasification

$$C + H_2O \rightleftarrows CO + H_2$$

Finally, hydrogen is required for catalytic hydrogenation, a field that is becoming increasingly important due to the development of asymmetric methods.

4.3. Hydrides

Hydrides (→ Hydrides) can be subdivided into four classes: ionic, metallic, covalent, and complex [1]. Ionic hydrides are formed at moderately high temperature from alkali or alkaline-earth metals and hydrogen. They crystallize in ionic structures of stoichiometric composition and yield hydrogen at the anode on melt electrolysis. The hydride ion that is formed has a standard electrode potential of −2.25 V in the $2H^-/H_2$system and is one of the strongest reduc-ing agents. Transition metals absorb fairly large amounts of hydrogen at elevated temperature and form metallic hydrides of sometimes variable composition (palladium absorbs approximately a thousand times its volume of H_2). Covalent hydrides contain definite bonds between hydrogen and an element of groups 13 – 17. Among the covalent hydrides, boranes, silicon hydrides, tin hydrides, hydrazines, and phosphines are suitable for reduction. Of the complex hydrides, sodium borohydride and lithium aluminum hydride are especially important reducing agents. Like the structurally similar compound lithium gallium hydride, they consist formally of the tetrahedral MH_4^- anion and a cationic counterion. A fine gradation in reactivity can be achieved by replacement of one or several hydride ions in the MH_4^- complex by other ligands. Table 2 illustrates the numerous reduction capabilities of well-known, commercially available complex and covalent hydrides.

Alkali and Alkaline-Earth Hydrides. Metal oxides and metal halides with suitable redox potentials can be reduced to the elementary metals with sodium and calcium hydrides. In the Borol process, NaH serves as reducing agent in the synthesis of sodium borohydride, while lithium aluminum hydride can be prepared from LiH and $AlCl_3$. Lithium hydride reduces carbonyl groups and olefinic double bonds in the presence of transition-metal chlorides [202], whereas NaH in complex mixtures of metal salts and alkoxides is used for the reduction of a number of functional groups [203]. Comparative investigations on LiH, NaH, and KH reveal interesting effects in the reduction of double bonds, depending on experimental conditions [204]. The activity of MgH_2, like that of other saltlike hydrides, depends strongly on the method of preparation [205]. In combination with various alkoxides and dialkylamines, MgH_2 can stereoselectively reduce monocyclic and bicyclic ketones to the corresponding alcohols [206].

Organoboranes, Diborane, and Borane Adducts. Organoboranes and borane adducts, preferably in combination with amines, mercaptans, and ethers, are reducing agents with a wide range of applications in dehalogenation, ether cleavage, deoxygenation, and epoxide ring opening, as well as in the reduction of sulfur and nitro compounds, imines, oximes, aldehydes, ketones, carboxylic acids, acid chlorides, anhydrides, lactones, amides, quinones, alkynes, and olefins [207–213]. (Regio)selective reductions can be achieved with sterically demanding organoboranes [214], such as dicyclohexylborane [92], [215], 9-borabicyclo[3.3.1]nonane [216], diisopinocampheylchloroborane[217], thexylborane [207], borane complexes of sterically hindered tertiary amines [218], [219], or borane pyridine complexes [220]. Catechol borane exhibits lower reactivity [221], [222]. Catechol borane also permits stereoselective reduction of β-hydroxyketones to syn-1,3-diols, whose diastereoselectivities can be increased still further by addition of Wilkinson's catalyst [223]. Very mild deoxygenations can be carried out by bis(benzoyloxy)borane reduction of the corresponding tosylhydrazones [56].

An interesting development is the synthesis of synthetically relevant organoboranes by sonochemical methods [18], [224]. The advantages of ultrasound treatment in the synthesis of various organoboranes from olefins and borohydride adducts include higher yields and substantially reduced reaction times.

Organosilanes. Organosilicon reducing agents [225] have increased greatly in importance, partly due to the fact that they often enable highly stereospecific reactions to be carried out. The use of chirally substituted metal complexes as catalysts permits the enantioselective hydrosilylation of prochiral alkenes, carbonyl compounds, and imines [226], [227]. Tetrabutylammonium fluoride (TBAF) catalyzes the diaste-

reoselective reduction of ketones with diphenylmethylsilane or dimethylphenylsilane [228].

Triethylsilane, sometimes in combination with activators such as protic acids or Lewis acids, reduces lactones, halides, alcohols, nitriles, and diazonium salts [229–231].

Trimethylsilylsilane deoxygenates thiocarbamate derivatives of alcohols in a radical chain reaction[232].

Organotin Hydrides. Among the organostannanes, tributyltin hydride plays a very important role, its principal use being the reduction of organic halides to hydrocarbons via a radical chain mechanism [187], [233–235]. The tin-hydride-reduced intermediates produced by radical generation from halides, alcohols, carbonyl compounds, nitro components, sulfides, and selenides can be used for various consecutive reactions, particularly ring closure [236]. Reduction with tributyltin hydride also makes accessible compounds such as larger ring systems that are otherwise difficult to obtain [237]:

Reductive C – S cleavage of suitably substituted monocyclic azetidinones with tributyltin hydride leads via intramolecular ring closure to carbacepheme bicyclic [238]. Organotin hydrides react, analogously to hydrosilylation, with alkenes and alkynes under hydrostannylation. The mild reaction conditions lead to chemoselective hydrogenation of activated C–C multiple bonds with the preservation of CO and CN double bonds. Recent developments involve the binding of tin hydrides to polymer carriers to produce renewable and easily manipulable reducing agents that can be employed in economical cyclic processes [239].

Complex Borohydrides. Among the borohydrides, sodium borohydride alone or in combination with other metal ions or complex-forming agents is extremely important because of its versatility [40]. With a hydrogen content of 10.2 wt % and a redox potential of −1.24 V, it is an advantageous, specific, and highly selective hydrogenation agent that can also be employed in protic solvents, although with gradual decomposition [240]. In addition to its use as a universal reducing agent, $NaBH_4$ can be used to trap traces of aldehydes, ketones, and peroxides; as a source of pure hydrogen in fuel cells; as an additive in vat dyeing; and for nickel – boron deposition (Nibodur process).

Table 3 illustrates how the reactivity and selectivity of reductions with $NaBH_4$ can be varied by appropriate choice of solvent [40].

In addition to the choice of $Ca(BH_4)_2$, $LiBH_4$, tetraalkylammonium borohydrides, and $Zn(BH_4)_2$ [241–246], combinations of $NaBH_4$ or $LiBH_4$ with $TiCl_4$, $Ti(OR)_4$, $CeCl_4$, Cu_2Cl_2, $CuCl_2$, $CuSO_4$, $ZnCl_2$, ZnI_2, $Ni(CH_3COO)_2$, $ZrCl_4$, $PdCl_2$, $RhCl_3$, Se, I_2, H_2SO_4, CF_3COOH, or $ClSi(CH_3)$ are also suitable for fine adjustment of reactivity [98], [219], [247–259] and for the reduction of nitriles, imines, anhydrides, esters, carboxylic acids, hydrazones, and olefins. A further gradation of the redox potential can be achieved by changing the ligands on boron. The range of reactants extends in this case from stable alkali metal and tetraalkylammonium borohydridoacetates, through the corresponding cyanides, to the highly reactive alkylhydridoborates [25], [44], [260–267].

In enantioselective variants, chiral metal semicorrin or bisoxazoline complexes are added in substoichiometric amounts along with $NaBH_4$ to reduce unsaturated systems with high optical yields [268]. Chiral β-sulfinylenamines are converted diastereoselectively by $NaBH_4$,$Zn(BH_4)_2$, or Bu_4NBH_4 in the presence of excess acetic acid to the corresponding erythroamines [252]. Finally, ketoxime *O*-alkyl ethers can be reduced to amines by $NaBH_4$–$ZrCl_4$ in the presence of chiral 1,2-aminoalcohols with good enantiomeric excess values and high yields [249].

Lithium Aluminum Hydride. Like sodium borohydride, lithium aluminum hydride, which contains 11.5 wt % hydrogen, is one of the most versatile reducing agents. It can reduce virtually all heteroatom – carbon double bonds with the preservation of nonpolarized olefinic double

Table 3. Reduction with $NaBH_4$ in different solvents *

	$NaBH_4$ in various solvents	$NaBH_4$+ LiCl, diglyme/THF	$NaBH_4$+ $AlCl_3$, diglyme	$NaBH_4$+ BF_3, diglyme	$NaBH_4$+ $BF_3 \cdot Et_2O$, THF

bonds [269]. For example, nitro compounds, nitriles, amides, lactams, imines, and oximes can be reduced to amines; carboxylic acids, esters, acid chlorides and anhydrides, ketones, aldehydes, and epoxides can be reduced to alcohols; oxygen – sulfur compounds and disulfides, to sulfides and thioethers; phosphine oxides to phosphines; and hydrazones and hydrazides to hydrazines (see also Table 1). Hydroxylamides of amino acids are converted to labile aminoaldehydes with preservation of the optical activity [101]. On reduction with $LiAlH_4$, various substituted acetylene dicarbinols yield *trans*-configured, conjugated double bonds [270], which permits the synthesis of polyolefinic natural substances [271]. For example, 2,6-dimethylocta-1,7-diene-4-yne affords cosmene (2,6-dimethylocta-1,3,5,7-tetraene).

The reactivity of $LiAlH_4$ can, like $NaBH_4$, be modified considerably by combination with bases or acids. Well-investigated (Lewis) acids include $AlCl_3$ for hydrogenolysis [62], [272]; silver salts [273], [274], and $CeCl_3$ [275] for reductive dehalogenation and reduction of phosphine oxides; LiI for stereoselective reduction of β-alkoxyketones [276]; and hydrogen halides for reductive halogenation of aromatic carbonyl compounds [277]. The addition of amines such as triethanolamine for the reduction of aminoesters and formamidines [278], diethylamine for the synthesis of aldehydes from esters [279], or trialkylamines for the highly selective reduction of acid chlorides, nitriles, and amides in the presence of nitro groups and halides [280] have all proved successful.

In enantioselective variants, 3-ketoesters are reduced to chiral 1,4-diols under the asymmetric induction of a remote group [281]. Early investigations of the mechanism of $LiAlH_4$ reduction of carbonyl groups were carried out by FELKIN et al. [282] and compared with the corresponding Cram models of the relevant transition states, to allow reliable stereochemical predictions to be made. Other mechanistic investigations have dealt with the $LiAlH_4$ reduction of alkenes catalyzed by low-valence titanium and uranium compounds [283], [284].

Other Aluminum Hydrides. In addition to $LiAlH_4$, diisobutylaluminum hydride (DIBAH) is one of the most frequently used complex aluminum hydride reducing agents. It covers nearly the same range of reactions as $LiAlH_4$ but, by virtue of its specific reduction mechanism, can lead to regiospecifically or stereospecifically different products and thus represents an interesting alternative [87]. Other derivatives of $LiAlH_4$ include lithium *n*-butyldiisobutylaluminum hydride for the selective reduction of enones, disulfides, and other functional groups , lithium *tert*-butyldiisobutylaluminum hydride for the stereoselective reduction of cyclic ketones [286], and lithium tris[(3-ethyl-3-pentyl)oxylaluminum hydride for the chemoselective reduction of aldehydes in the presence of ketones [287]. $NaAlH_4$ can be used in combination with $AlCl_3$ and bases [288], whereas $NaAlH_2$–$(OCH_2CH_2OCH_3)_2$ (Red-Al) is used for the release of amines from sulfonamides [289], stereospecific reduction of propargyl alcohols [290], and regioselective epoxide ring opening [291].

Triphenylphosphine Copper(I) Hydride. The stable hexameric compound triphenylphos-

phine copper (I) hydride had been characterized as early as 1971 [292] but was recognized only in 1988 as a valuable stoichiometric reducing agent. Unsaturated ketones, aldehydes, and esters are hydrogenated with good stereoselectivity and excellent chemoselectivity at the activated C – C double bond [293], [294], and alkynes are converted to *cis*-olefins [295]. Catalytic reductions with triphenylphosphine copper chloride under hydrogen pressure interestingly follow a (stereo) chemically nonuniform course [296].

4.4. Metal Carbonyls

The simple and inexpensive methods of preparation of many metal carbonyls from elemental metal and carbon monoxide, by reduction of metal salts in the presence of carbon monoxide, or by oxidation of carbonyl metallates, together with their multiplicity of highly specific reaction capabilities, makes them ideal reducing agents. The formation and decomposition of $Ni(CO)_4$ to obtain high-purity nickel in the Mond nickel process is an industrial example of their use [199]. The inexpensive $Fe(CO)_5$ [297] deoxygenates epoxides to olefins [298] and

sulfoxides to sulfides [299], hydrogenates α,β-unsaturated carbonyl compounds [300], and decarbonylates aldehydes to hydrocarbons [301]. The carbonyl metallate $Na_2Fe(CO)_4$ (Collman's reagent) obtainable from $Fe(CO)_5$ is also a very selective reducing agent that, in particular, can reduce organic halogenated compounds and perform numerous functional group conversions [95]:

Cobalt carbonyls reduce unsaturated aldehydes [302]; chromium carbonylates hydrogenate α,β-unsaturated carbonyl compounds, imines, and nitriles [303]; molybdenum carbonyl desulfurizes thioethers [304], and dehalogenates α-haloketones, as does the binuclear compound diiron nonacarbonyl [305].

4.5. Metals

Lithium. Lithium can be used as a reducing agent in a number of reactions. In addition to the formation of $LiAlH_4$ from the elements, it is used in the reduction of hydrogen to LiH. The Birch reduction of aromatic ring systems with alkali metals yields partially hydrogenated, nonconjugated olefinic products [306]; the use of lithium instead of sodium suppresses the formation of side products.

In some cases, nitrile groups can be completely eliminated by lithium [308]. Reductive dehalogenation takes place smoothly [309], as does the formation of organolithium compounds by halogen – metal exchange reactions with halides [310]. Reductive cyclopropane ring opening [14], ether cleavage [310], and ester, alcohol, or thiol reduction [36], [93], [311] also be performed with lithium. The mechanism and stereochemistry of the reduction of cyclic ketones with alkali metals have been investigated in detail [312]. Like other strongly electropositive metals, lithium cleaves the C – S bond in sulfides, sulfoxides, sulfones, and thioketones.

Sodium. Sodium metal is used in the borosilicate process for producing $NaBH_4$ ($\rightarrow$ Hydrides).

$$Na_2B_4O_7 + 7\,SiO_2 + 8\,H_2 + 16\,Na \longrightarrow 4\,NaBH_4 + 7\,Na_2SiO_3$$

Because of its redox potential, sodium can release other metals such as strontium, barium, beryllium, and titanium from their salts. The reduction of SO_2 to sodium dithionite by sodium amalgam is decreasing in importance because of the trend toward mercury-free chlor-alkali electrolysis processes. Sodium amalgam is used for desulfonation [174] and for the synthesis of various carbonyl metallates. Birch reduction by sodium – potassium alloys can be followed by sp^3 C–C bond cleavage [313]. Partial hydrogenation by Birch reduction is one of the

best-known reactions; it involves sodium dissolved in ammonia or amines [306]. In addition to the stepwise reduction of aromatics, especially those with sensitive substituents, conjugated double bonds, triple bonds, or carbonyl groups can also be reduced. Magnetic and spectroscopic investigations indicate that solvated electrons are the actual nucleophilic reagents. An alcohol is often added as a proton source, which is also intended to buffer the solution to suppress undesired isomerization. Carboxylic esters, acid chlorides, and nitriles are reduced in alcoholic solution to the corresponding alcohols and amines. This Bouveault – Blanc reduction is used industrially to synthesize fatty alcohols from glycerides; however, it is increasingly losing its preparative importance due to the use of $LiAlH_4$ [314]. In the absence of an alcohol this reaction leads to an acyloin condensation.

The symmetrical coupling of alkyl halides, known as the Wurtz reaction, to form higher hydrocarbons is now of only minor synthetic importance; in addition to sodium, it can be carried out with lithium, silver, copper, aluminum, zinc, tin, or magnesium [315].

In the synthesis of polyenes, Na(Hg) is used in a modified Whiting reaction [270] for the stereospecific synthesis of *cis*- and *trans*-galbanolenes [(*E, E, Z*)- and (*E, E, E*)-1, 3, 5-undecatriene, respectively) via reductive elimination of dibenzoates [316]. The galbanolenes are important raw materials fo perfumes.

Potassium. Like sodium, potassium is produced by the electrolysis of its molten hydroxide. BERZELIUS first succeeded in obtaining elementary silicon in 1822, by reduction of silicon tetrafluoride with potassium. Because of its extreme reactivity, elemental potassium is rarely used for selective reduction reactions. It can be used as an alloy with sodium or alone for Birch reduction (see above). In the presence of crown ethers, potassium reduces alkyl fluorides and chlorides [317], as well as nitriles [318]. Ethers are reductively cleaved by potassium to give the corresponding hydrocarbons [43]. All higher alkali-metal organyls exhibit this ether cleavage reaction via α-metallation, particularly with cyclic ethers. Finally, nonplanar $4n$ antiaromatics can be converted to planar $(4n+2)$ Hückel aromatics by reduction with potassium [319].

Magnesium. The most important use of magnesium in preparative organic chemistry is the reductive formation of Grignard compounds from organic halides with umpolung of the halogen-bearing carbon atom. Grignard compounds can therefore be used as nucleophiles or as reducing agents.

The Nalco process, which has decreased in importance, combines electrochemical steps with the prior reduction of ethyl chloride by magnesium:

$$2\,C_2H_5MgCl + 2\,C_2H_5Cl + Pb \longrightarrow (C_2H_5)_4Pb + 2\,MgCl_2$$

The Kroll process uses magnesium to prepare titanium from $TiCl_4$; similar reductions yield metals such as zirconium, hafnium, and beryllium. Aldehydes and ketones can be coupled reductively with magnesium to form pinacols. Halides can be converted to the corresponding hydrocarbons via Grignard compounds, which also allow selective access to deuterated compounds [320]. Magnesium also permits the reduction of oximes, nitro compounds, and other functional groups [321] and the chemically selective reduction of conjugated C – C double bonds [322].

In the presence of chlorotrimethylsilane, magnesium leads to reductive cross-coupling of aryl acrylates with aldehydes, giving γ-lactones in moderate to very good yield [323].

Calcium. Calcium is used in metallurgy as a deoxidizing agent for copper, beryllium, and steel (together with silicon) [324], as well as to reduce metals such as zirconium, thorium, vanadium, and uranium. In the manufacture of vacuum tubes, calcium acts as a residual gas getter by forming the corresponding oxides, nitrides, and hydrides. Calcium plays only a minor role in organic synthesis. Like lithium and sodium, it can be used for reduction in liquid ammonia [325]; even difficultly reducible steroid ketones give good results [326]. In the same solvent, calcium also deoxygenates acylated α-hydroxyketones [327].

In the presence of ethylenediamine, calcium reduces epoxides to alcohols [328]. Car-

bocyclic and heterocyclic aromatics can be dehalogenated by calcium [329] or converted to Birch-type reduction products [330], [331].

Aluminum is obtained industrially by molten salt electrolysis. It reacts with hydrogen and lithium metal to give $LiAlH_4$. In the Ziegler direct process (→ Aluminum Compounds, Organic, Chap. 1.), aluminum preactivated by titanium is converted with alkenes to give organoaluminum compounds, which in turn serve as valuable reducing agents (e.g., in hydroalumination reactions). In aluminothermic processes (→ Aluminothermic Processes), aluminum liberates elements such as iron, chromium, manganese, titanium, or silicon from their oxides by virtue of its high oxygen affinity. Aluminum amalgam reductively cleaves sulfoxides [180] and leads to pinacol coupling of aldehydes or ketones [332]. In acid solution, aluminum reduces nitro compounds to oximes and amines.

Silicon. In contrast to its organic compounds, silicon is rarely used as a reducing agent, and its principal importance now is as a raw material in the production of silicon chips in microelectronics. Silicon is obtained by reducing silicon dioxide with carbon in a submerged arc furnace and is then purified by zone melting. Like aluminum, it is employed in thermal reduction processes for high-melting metals.

Tin. In organic chemistry, tin has become one of the less common reducing agents. The use of tin in industrial processes is becoming questionable for ecological and economic reasons since it has an unfavorable ratio of reduction capacity per unit mass and the resulting tin salts are toxic.

The conversion of nitro compounds or imines to amines is one of the classic uses of tin reduction [333]. Dinitro compounds can also be converted successfully to diamines [334]. Tin amalgam reduces conjugated enediones smoothly to saturated diketones [335], while mixtures of tin and aluminum assist the regioselective aldol addition of allyl halides to various aldehydes [336–338]. The selectivity of the reductive allylation of aldehydes in the presence of ketones can be enhanced by ultrasound treatment of the tin- containing mixture [339]. Finally, organotin halides are formed by direct reduction of alkyl halides with tin and can be converted directly to organotin hydrides, whose use as specific reducing agents is increasing.

Iron. The Bechamp reduction [340] of aromatic nitro compounds to the corresponding amines is one of the best-known organic reactions involving iron. Systematic investigations of this type of reaction show that it is a useful alternative to catalytic hydrogenation [341] because of the simple reaction control, price, and position of iron in the electrochemical series.

$$Fe \rightleftharpoons Fe^{2+} + 2e^-;\ E_0 = -0.44\ V$$

$$Fe^{2+} \rightleftharpoons Fe^{3+} + e^-;\ E_0 = +0.77\ V$$

The low expenditure on apparatus and equipment is, however, offset by problems arising in the separation and removal of the iron salts formed. The reactivity of iron can be modified by various solvents, impurities in iron, and its active surface. The reduction of nitro compounds can, because of its strong pH dependence, be directed selectively to the azoxy, azo, or hydrazo intermediates.

Iron powder effects the reductive coupling of allyl halides to nonconjugated dienes [342] and plays a major role in the cleavage of S – S bonds and in the reductive dehalogenation of homocyclic and heterocyclic compounds. An interesting reducing agent is iron graphite ($C_{24}Fe$), formed from potassium graphite (C_8K) and $FeCl_3$, and used for the *anti*-debromination of vicinal dibromides [28]. Because it is economical, iron can be used in metallurgy to precipitate more electropositive metals from their salt solutions (cementation). Processes have been developed for precipitating heavy-metal impurities from effluents onto rusty iron.

Zinc is one of the oldest and most widely used reducing agents in organic chemistry, and is the reducing agent in a number of named reactions. In the Clemmensen reduction [343], acid-stable ketones and aldehydes can be converted with zinc amalgam to hydrocarbons.

The acid concentration and the choice of solvent are often decisive with regard to reaction course. Other metals give very poor yields in this four-electron transfer.

In the Reformatzky reaction[345],α-halocarboxylic esters undergo reductive condensation with carbonyl compounds in the presence of metallic zinc to give β-hydroxyesters or olefins.

The Simmons – Smith reaction [347] is used to synthesize cyclopropanes by treating olefins with zinc – copper-reduced diiodomethane.

Among a large number of reducing agents, zinc in sodium hydroxide has proved effective in converting nitro compounds to azo components [144]. Furthermore, zinc is suitable for the reduction of nitriles, the reductive cleavage of C – S and C – Hal bonds, the synthesis of *cis*-olefins from alkynes (Rieke zinc [349], [350]), and opening epoxide rings [351]. In the presence of catalytic amounts of aquocobalamin, zinc reduces nitriles smoothly to aldehydes [352]. Metal salts such as $HgCl_2$, CuI, and $NiCl_2$ are often added to activate zinc. A combination of zinc, $NiCl_2$, and ultrasound hydrogenates conjugated unsaturated carbonyl compounds [353–355].

Nickel. A particularly active form of nickel is Raney nickel, a pyrophoric catalyst formed by etching the inactive aluminum component from a nickel – aluminum alloy with alkali. It can be used for catalytic hydrogenation or directly as a reducing agent. The hydrogenative hardening of oils (→ Fats and Fatty Oils, Chap. 8.) in the food industry is the best-known industrial process involving Raney nickel. In organic chemistry, Raney nickel is used mainly as a reductive desulfurizing agent.

The Wolfrom – Karabinos reduction of carbonyl compounds with Raney nickel via intermediate thioketals or thioacetals is particularly suitable for acid-labile and base-labile compounds [358]. In the synthesis of the non-opiate alkaloid epibatidine, Raney nickel is used to carry out a reductive dehydroxylation at a quaternary carbon center [359]. Nickel – aluminum alloys reduce pyridines, quinolines, isoquinolines [129], [360], and nitroso compounds [361]. Activated nickel dehalogenates *o*-dihaloxylylenes [362]. Nickel – graphite, obtained from $NiBr_2$ and C_8K, reduces alkynes to *cis*-olefins [363].

Copper. In addition to the aforementioned Simmons – Smith reaction, copper is used particularly in reductive dehalogenation. The Ullmann reaction [364] utilizes this property in the synthesis of bisarylenes from corresponding aryl halides [33]. An analogous coupling of halides with phenol derivatives yields bisaryl ethers. The treatment of nitrohalo aromatics with copper powder in molten benzoic acid yields nitro aromatics [365]. Activated copper reacts with epoxyalkyl halides to form the reduced epoxyalkylcopper reagent, which reductively cleaves the epoxy ring with intramolecular cyclization [366].

Copper(0) isonitrile complexes allow the synthesis of ring systems from olefins and halides in a Simmons – Smith-type reaction [367], and reduce dibromocyclopropanes to allenes [368].

4.6. Metal Salts

The importance of low-valence metal ions as reducing agents has gradually shifted from stoichiometric reactions to catalytic applications. In this way the selective, fast, and frequently quantitative reductions with low-valence metal ions can be combined with their regeneration by cheaper, less toxic, or more easily manipulable reducing agents in a cyclic process. Often only the combination of redox systems can produce the desired reaction, or particularly reactive species may be formed by in situ reduction. The rapid and quantitative redox reactions of metal salts make them attractive for analytical chemistry (e.g., titanometry) and for inorganic systems [369], as well.

Low-Valence Titanium Ions. The best-known reaction of titanium species in oxidation states 0 to +2 is reductive dimerization of carbonyl compounds to vicinal diols or olefins (McMurry reaction) [53], [370].

Low-valence titanium is generated in situ from $TiCl_3$ or $TiCl_4$ and K, Mg, Zn–Cu, Zn, or $LiAlH_4$. ESR investigations confirm the occurrence of radical intermediates during the redox reaction. Aldehydes, ketones, esters, and amides are reduced at the carbonyl group to olefins by the Tebbe–Grubbs reagent, prepared from $TiCl_3$–Zn–CH_2Cl_2. Alkynes can be reduced by $TiCl_4$–$LiAlH_4$ to *cis*-alkenes or alkanes [371], while $TiCl_3$–$LiAlH_4$ dehalogenates vicinal dihaldes and bromohydrins [372], [373]. 1,3-Diols are reduced to cyclopropanes, oxiranes are deoxygenated, thioketols are desulfurized, and N–O bonds are reductively cleaved [374].

The reduction of acetals with $TiCl_4$/$LiAlH_4$ leads to pinacol coupling and formation of ethers and alkenes [375].

Vanadium(II) and Niobium(III) Salts. In addition to the reductive removal of hydroxyl groups from acyloin derivatives [376], the transformation of keto groups to quaternary carbon centers [377], and the reductive cyclisation of enals and ynals [378], Vanadium(II) salts have a major potential for the reductive pinacol coupling of aldehydes and ketones [379–381]. This method is also highly suitable for the diastereoselective reductive coupling of peptide alcohols to give C_2 symmetrical HIV protease inhibitors [382]. Niobium(III) salts are also suitable for pinacol coupling, albeit with lower yields [383–386]. They can be used for reductive coupling of imines with aldehydes to give 2-amino alcohols [387]. The related homocoupling of nitriles or silylated imines to afford vicinal diamines is catalyzed by niobium(IV) [388]. Mixtures of $NbCl_5$ or $TaCl_5$ with zinc reduce alkynes to (*Z*)-alkenes [389].

Chromium(II) Salts. Chromium(II) compounds reduce many alkynes stereospecifically to *cis*-olefins, hydrogenate conjugated double bonds, act as dehalogenating agents, convert geminal dibromocyclopropanes and vicinal dihalo alkenes to allenes, and reduce nitro and diazo compounds, as well as epoxides [374].

Iron(II) Salts. The Fe^{2+}/Fe^{3+} redox potential is strongly pH dependent and becomes more positive in acid solution but more negative in alkaline solution. Hence, sensitive nitro compounds can be reduced in basic solution to amines [390].

Mixtures of $FeCl_3$, hydrides, and alkoxides can reduce halides, ketones, alkenes, and alkynes [391]. Organic nitriles can be reductively decyanated with $Fe(acac)_3$/Na [392].

Lanthanide Salts. In the past few years the numerous reduction possibilities of various lanthanide reagents, particularly SmI_2, have been studied in detail [55], [393]. The reactions range from the reduction of unsaturated systems with ytterbium in liquid ammonia to $NaBH_4$ or $LiAlH_4$ reduction of carbonyl-containing substrates, other oxygen-containing compounds, or halides, mediated by $LaCl_3$, $ErCl_3$, SmI_3, and in particular, $CeCl_3$. The increasing area of application of samarium(II) salts is particularly important with regard to a stereochemically uniform reaction [396–398]. In addition to the reduction of nitrogen-containing functional groups, and deoxygenation or dehalogenation reactions, it is used increasingly for Barbier-, Wurtz-, and pinacol-type C–C coupling. Stereocontrolled intramolecular variants of these coupling reactions provide a synthetic route to complex cyclic natural products [399]:

Mixtures of ethylmagnesium bromide and samarium(III) or ytterbium(III) triflate lead to reductive pinacol couplings of aldehydes and ketones that are even more efficient than with SmI_2 [400], [401].

4.7. Nonmetallic Inorganic Reducing Agents

Sulfides, Selenides, and Tellurides [9], [144]. Hydrogen sulfide and the metal sulfides are among the oldest known reducing agents [402], which includes their use in metallurgy and as analytical reagents [403]. They reduce quinones to hydroquinones and azides to amines, as well as reducing sulfur compounds in higher oxidation states, such as disulfides, sulfonyl chlorides, and thiocyanates. Sodium sulfide reduces aromatic or aliphatic nitro groups selectively depending on the amount of water added [404] and can be used for the isomerically pure reduction of aromatic nitro compounds and anilines [405]. Thiols dehalogenate α-haloketones and deoxygenate aromatic ethers [9]. Nitroaromatic compounds are also reduced by ammonium sulfide (Zinin reduction) [406], low-valence selenium compounds [407], H_2Te and its salts, and various organotellurides [9].

Sulfur Dioxide and Sulfites. Sulfur dioxide or sulfites [406] reduce quinones to hydroquinones, ozonides to the bisulfite adducts of the corresponding aldehydes, hydroperoxides to alcohols, diazonium salts to hydrazines, and sulfonyl chlorides to sulfinic acids. In the Piria reduction [408], nitroaromatic compounds are converted to amines and aminosulfonic acids.

Dithionite. Sodium dithionite, $Na_2S_2O_4$, reduces diaryl disulfides to thiophenols, diazonium salts to arylhydrazines, azo components and nitrosoaromatic compounds to amines, quinones to hydroquinones, aliphatic nitro compounds to oximes, and aromatic nitro compounds to amines [406]. Unsaturated ketones are regiospecifically converted by $Na_2S_2O_4$ to saturated carbonyl compounds [12]. Excess rongalite ($HOCH_2SO_2Na \cdot 2\ H_2O$) reduces tellurium in basic solution to the reducing agent Na_2Te [409]. In analysis, dithionite is used as an absorption agent for oxygen. Dithionite and rongalite areused industrially in vat dyeing and as bleaching agents in the paper industry.

Sodium Thiosulfate. $Na_2S_2O_3$, which is prepared from sodium sulfite and sulfur, is used in photography as a complex-forming agent for unreacted silver halide. In bleaching it is used as a reducing antichlorine agent to remove chlorine residues from chlorine-bleached fabric. In iodometry, oxidation equivalents are determined by titration with $Na_2S_2O_3$.

Hydrazine. Hydrazine decomposes in the presence of palladium, platinum, or nickel catalysts into its elements or ammonia, which makes it a convenient source of hydrogen for hydrogenations [410]. The amount of hydrogen released increases with increasing pH of the solvent. Hydrazine can reduce some metal ions to the elements.

Hydrazine reduces ketoximes and nitroaromatic compounds to the corresponding amines, nitriles to hydrazonimines, sulfonyl chlorides to disulfides, and halides to hydrocarbons [8], [9], [410]. Its most important role, however, is in the conversion of carbonyl to methylene groups (Wolff – Kishner reduction).

In the Huang – Minlon variant of this reaction the intermediate hydrazone is heated in situ in a high-boiling solvent and converted to the methylene compound. Depending on the stability of the hydrazones, various solvents and bases can be used for their decomposition [9]. In terms of batch scale-up, this variant is often superior to the Clemmenson reduction. The base-catalyzed tosylhydrazone cleavage of carbonyl compounds, known as the Bamford – Stevens

reduction, may also be used for the reductive preparation of olefins from the latter [412].

Diimine. The synthetic potential of N_2H_2 [413] was recognized relatively late, although examples of the reduction of olefinic double bonds in the presence of hydrazine were already known. Diimine, obtained by oxidation of hydrazine with oxygen or H_2O_2, acid hydrolysis of azodi-formate, or decomposition of various sulfonyl hydrazides, reduces C – C double and triple bonds, as well as aldehydes, ketones, and imines. Diimine formed in situ is also suitable for the reduction of highly sensitive endoperoxide olefins [414]:

Alkynes are reduced to *cis*-alkenes or alkanes depending on the substituents. Since diimine reduction proceeds under very mild conditions, it preserves a number of functional groups that are attacked during catalytic hydrogenation or by other reducing agents. Allyl halides, esters, and disulfides are thus retained, as are the labile N–O and N–N–O groups [413].

Phosphorus, Phosphines, and Phosphites. Phosphorus is often used in combination with I_2 or HI as a reducing agent. Nitroaromatic compounds are reduced in basic solution by white phosphorus to the azoxy components or amines [415]. Mixtures of red phosphorus and I_2 act as deoxygenating agents and can therefore reductively open lactone rings [416]. Red phosphorus in hydroiodic acid reduces azlactones, dehalogenates aromatic compounds, and deoxygenates hydroxy fatty acids [333]. P_2I_4 reduces dithioacetals to thioethers [417]. Triphenylphosphine [418], because of its high affinity for oxygen and sulfur, is a universal reducing agent. It is a dehalogenating and deoxygenating agent; reduces diaryl sulfides to thiols; and desulfurizes sulfenyl chlorides to the corresponding alkyl chlorides, and sulfur- containing heterocyclics to olefins. Azides are converted by hydrolysis of the intermediate iminophosphines (Staudinger reaction) into amines. In combination with iodine, triphenylphosphine reduces sulfoxides to thioethers and aromatic sulfonic acids to thiols. A combination of triphenylphosphine, iodine, and imidazole reduces vicinal diols to olefins. In the Wittig and Wittig – Horner reactions, triphenylphosphine and other phosphine or phosphite analogues are formally used as reducing agents in the synthesis of olefins from carbonyl compounds and phosphorus ylids.

Trialkylphosphites have a broad range of applications similar to those of triphenylphosphine, and to some extent they complement the properties of the latter. The most commonly used member of this class, triethylphosphite [418], is the classic reagent for desulfurizing cyclic thiocarbonates in the Corey – Winter method for obtaining olefins from vicinal diols. Triethylphosphite is used for reductive photochemical sulfur extrusion in paracyclophane syntheses [419]; it reduces halogenated compounds, hydroperoxides, and oxiranes, as well as nitro and nitroso compounds.

Hypophosphoric Acid. In the presence of Raney nickel, H_3PO_2 reduces nitriles to aldehydes [110], while with Pd – C catalysis, olefinic double bonds are hydrogenated and organic halides are reduced [420]. Aromatic amines can be reduced via their aryldiazonium salts to aromatic hydrocarbons [9].

Hydroiodic Acid is used in combination with phosphorus to reduce a wide range of functional groups (see phosphorus,page 23). It also reduces vicinal diketones and α-hydroxyketones to monoketones, and aromatic sulfonyl chlorides to diarylsulfides [157]; it hydrogenolytically cleaves halogen and silyl groups [333]. Substituted dihydroxyaromatic compounds are reduced to hydrocarbons [421]. Sodium iodide in the presence of various activators reduces α-haloketones to ketones [9].

4.8. Carbon Compounds

4.8.1. Carbon Monoxide

Carbon monoxide owes its outstanding industrial importance as a reducing agent to processes for winning iron and some other metals (see page 19). Furthermore, CO provides access to metal carbonyls, which can be used themselves as reducing agents or as hydrogenation catalysts (see Section 4.4).

Carbon monoxide can be reductively inserted into carbon – halogen bonds [422]. In the presence of various organometallic catalysts, CO reduces nitroaromatic compounds to amines; as a gas mixture with H_2S it represents a cheap alternative to hydrogen for converting dinitroaromatic compounds to diamines [423]. Reductive cyclization of *o*-nitrobenzaldehyde oximes with CO allows straight forward access to 2*H*-indazole derivatives [424]:

Catalytic reduction of nitroaromatic compounds with CO can also be directed to the isocyanate stage, which permits phosgene-free synthesis of these substances [425].

4.8.2. Formic Acid

In the presence of catalysts, formic acid reduces carboxylic acids and aromatic nitriles to aldehydes [157], [426], [427]. Enamines are reduced in good yields to amines, and activated C – C double bonds are reduced to saturated systems [418]. In the Leuckart – Wallach reaction, formic acid, its amide, or ammonium salt acts as a hydride donor in the reductive amination of carbonyl groups [428]. The special case known as the Eschweiler – Clark reaction uses formaldehyde as the carbonyl component and yields dimethylamines.

This reaction can also be used to synthesize nitrogen-containing ring systems from acyclic precursors [429]. Sodium formate reductively dehalogenates allyl chlorides to the corresponding olefins in a phase-transfer reaction with a palladium catalyst [430].

4.8.3. Carbonyl Compounds

Aldehydes generally exhibit a marked tendency to oxidize and form the more stable carboxylic acids. In the case of aldehydes that do not contain hydrogen on the α-carbon atom, disproportionation occurs to give the corresponding alcohol and carboxylic acid (Cannizzaro reaction) [52]. This base-catalyzed reaction can occur intermolecularly as well as intramolecularly, and in its crossed version using two different aldehydes leads, at most, to two redox pairs. α-Ketoaldehydes undergo intramolecular disproportionation to give α-hydroxycarboxylic acids.

Formaldehyde used in excess as reactant reduces the other aldehyde to alcohol and is itself converted to formic acid. With regard to industrial application of the Cannizzaro reaction, a wide range of catalysts have been tested so that enolizable aldehydes can also be used under neutral reaction conditions [431]. Formaldehyde is suitable for a number of other reductions, including the preparation of colloidal gold solutions and silver mirrors from the metal salts. It converts nitroaromatic compounds under hydrogenation conditions to alkylated amines [432]. Reductones, which in their tautomeric form also occur as enediols, represent another class of strongly reducing substances [433]. Biologically important members of these acyloins include, for example, the antioxidant vitamin C, which in biological systems is involved in the reductive removal of oxygen radicals.

4.8.4. Alcohols

In the classic Meerwein – Ponndorf – Verley process aluminum isopropoxide acts as a hydride donor in the reduction of ketones [434]. The consumed reducing agent is constantly removed from the reaction as volatile acetone. Acrolein is reduced by 2-propanol to allyl alcohol at elevated temperature in the presence of MgO – ZnO catalysts. Ethanol reductively cleaves aromatic diazonium salts to hydrocarbons, but other functional groups are not attacked. Azoxybenzenes are formed in the reduction of nitroaromatic compounds with benzyl alcohol [435].

Examples of the reductive action of amines analogous to that of alcohols are very rare, although this type of reaction is known as a side reaction in the treatment of simple aldehydes with lithium diisopropylamide [431]. In

the Shell H_2O_2 process (→ Hydrogen Peroxide, Chap. 4.2.), oxygen is reduced to hydrogen peroxide by catalytic H_2 transfer from 2-propanol. Other processes for producing H_2O_2 from oxygen utilize regenerable anthrahydroquinones (→ Hydrogen Peroxide, Chap. 4.1.).

4.8.5. Alkenes

Some alkenes are excellent hydrogen donors for catalytic hydrogenation and hydrogenolysis. Cyclohexene, which is normally used as a reducing agent with a palladium catalyst, is particularly important in this application [418]. Benzyl and benzyloxycarbonyl groups can be removed hydrogenolytically, whereas suitably substituted carbonyl groups can be reduced to methylene groups. Ketones, which are more difficult to reduce, can be reacted with the higher-boiling compound limonene as hydrogen donor. Dinitroaromatic compounds are converted to the corresponding diamines by cyclohexene.

Cycloheptatriene and some of its derivatives act as hydride donors toward many carbenium ions. These reduction mechanisms often proceed under heterogeneous catalysis and are of some industrial interest [431].

4.8.6. Heterocyclic Compounds

The driving force for many heterocyclic systems to transfer hydride ions is formation of the stable aromatic state. 1,4-Dihydropyridines, for example,the commercially available Hantzsch esters, hydrogenate hydride acceptors with the formation of pyridines. 1,4-Dihydronicotinamides and dihydroacridines reduce carbonyl and C – C double bonds. Normally however only electron-deficient double bonds react sufficiently fast under nonenzymatic conditions. In the presence of stoichiometric amounts of $Mg(ClO_4)_2$, optically active *N*-methyldihydropyridines reduce prochiral ketones to alcohols in high optical yields. Dihydropyrimidines and dihydropyrazines are used rarely for reductions because they are often too reactive and difficult to handle [431].

5. Special Reduction Methods

In addition to the aforementioned generally applicable reduction variants, other special procedures also exist, which however are often restricted for experimental reasons to specific applications. Some of these processes, for example, enzymatic reductions, will increasingly complement the general range of methods in the future and nowadays are already the methods of choice in specific problem areas. Pressing ecological and economic questions, as well as the increasing (stereochemical) complexity of chemical structures (e.g., crop protection agents, pharmaceuticals), make biocatalytic process control methods increasingly more advantageous.

Biomimetic Reductions [436]. The best-investigated model structures for simulating biologically relevant reductions are the 1,4-dihydronicotinamides and analogues, which are model compounds for studying NADH-mediated redox reactions. The reductions depend to a great extent on the solvent, the addition of salts, and photosensitizers; they are mainly restricted to allyl acetates.

Photoinduced Reductions. Alcohols, amines, sulfides,and hydrocarbons can transfer electrons to photochemically excited $\pi*$-orbitals of carbonyl compounds or heterocyclic compounds. Similar reductions of nitro, azoxy, and hydrazo compounds are also known [437]. Phenylmethanethiol is desulfurized by UV irradiation in the presence of triethylphosphite [438]. Photo-induced reductions are also used in reprography.

Enzymatic Reductions. Numerous review articles refer to the rapidly growing methods and preparative innovations in biocatalytic reductions [51], [439–445]. Bakers' yeast [446] is one of the most widely used biocatalysts and exhibits an extremely high substrate tolerance in the reduction of ketones and C – C double bonds, and in acyloin condensations [447]. In addition to the multiplicity of possible reactions, an attractive feature is the high enantiomeric and diastereomeric excesses that are obtained, which often can be achieved only with great difficulty by purely chemical methods. In general the most serious problems in enzymatic reduction appear

to be reproducibility, separation of the product from the culture medium, and sufficient purity of the enzymes. The range of applications can be further increased by the use of thermophilic enzymes or by controlled mutagenesis of the amino acid sequence of the active site [448].

Antioxidants. Under the prolonged action of oxygen, a wide range of substances can experience considerable reduction in quality due to undesirable autoxidation processes. To suppress these processes, reducing agents such as electron-rich phenols, hydroquinones, or amines are added to reductively trap peroxide radicals. In biological systems this protective function is performed by enzymes (superoxide dismutases, catalases, peroxidases), vitamins (ascorbic acid, vitamin A, vitamin E), and trace elements [449–454]. The above-mentioned three classes of enzyme catalyze the inactivation of reactive oxygen species such as O_2^- , $HO^\bullet$, H_2O_2, and peroxy radicals. Vitamins C and E act as $^1O_2$ traps, stabilize O_2^- and $HO^\bullet$ radicals, and inhibit the peroxidation of lipid membranes [455–457]. Ascorbic acid can also effectively reduce nitroxide radicals, which are isoelectronic with peroxy radicals [458].

In addition to being effective $^1O_2$ traps, carotinoids protect cells against harmful photooxidation and the action of photosensitizing agents [459]. Plant phenols can also act as antioxidants in other biological systems, e.g., inhibiting autoxidation of unsaturated lipids[460]. A "free-radical theory" explains the process of biological aging in terms of continuous oxidative damage to cellular compartments, caused by reactive oxygen- containing molecules [461, 462,462,463]. A series of biological observations have suggested a connection between aging processes and oxidative stress [462]. The sensitivity of the brain towards radicals is shown in modes of cerebral ischemia in which neuron damage is reduced by antioxidants [455]. An attempt has been made to explain the neurodegenerative Alzheimer's disease in terms of the oxidative, radical, cell-damaging activity of ß-amyloid protein fragments, which could possibly be prevented by prophylatic administration of antioxidants [464–467]. Many of the numerous organosulfur compounds found in garlic and onions have antioxidant activity. The physiological activity profile of Allium species is in part attributable to the reductive cell-protecting activity of certain components [468–470].

Reductive Combustion. A technically interesting method for reducing NO_x emissions from combustion processes is to react the nitrogen oxides with reducing agents such as CO and H_2 [471–479]. A process for the reductive decomposition of NO_x-containing gases with voltages in excess of 20 000 V is being tested. Nitrogen oxides disproportionate into their elements under the influence of high voltage. Technically, this process could be important in reducing emissions from fossil fuel power stations and automobiles [480].

Removal of NO_x by reduction with NH_3 (g) or aqueous NH_3 is known as selective catalytic reduction and is suitable for emission control in power stations, incinerators, glass-melting tanks, and combustion engines [474], [481] [482]. The degree of reduction depends on the nature of the catalyst and the temperature range [483], [484].

1. Introduction

Definitions. According to ISO/R 836, refractory materials are nonmetallic materials or products (including those containing a proportion of metals) having a minimum pyrometric cone equivalent of 1500 °C. Determination of the pyrometric cone equivalent (refractoriness) is described in ISO/R 528. Test pieces of the refractory material in the form of small cones are raised in temperature alongside reference pyrometric cones (blunt-tipped, skewed, triangular pyramids) with a defined temperature of collapse (softening).

Certain products from the refractory industry do not comply with this definition, however, but still fall under refractory classifications and are therefore conventionally termed refractories.

In the common sense, refractories are ceramic construction materials capable of withstanding temperatures above 800 °C. Numerous refractory compositions in a wide variety of shapes and forms are used in a broad range of industrial applications. The three main groups of refractory ceramics are:

1) Shaped refractory products (bricks)
2) Unshaped refractory products (monolithics)
3) Ceramic fiber products

Their three main applications are:

1) The construction of reaction chambers (e.g., furnaces)
2) Thermal insulation
3) Recycling of heat in regenerators or recuperators

10.1002/14356007.a23_001

The temperature of use for "hot face" linings ranges from ca. 800 to 1800 °C, and sometimes to 2000 °C or higher.

In addition to high temperature resistance, other essential properties for refractories are resistance to temperature change (thermal shock) and to mechanical and corrosive influences.

2. Historical Aspects

It is believed that the first baked refractory bricks were made from quartz-containing clays, either by the Phoenicians or the Chinese. For several centuries such prerefractory products were sufficient to meet the modest thermal requirements of small glass- or metal-melting furnaces. At the beginning of the nineteenth century the idea of adding prefired clay – the so-called *grog* material – to clay was shown to result in bricks with better dimensional accuracy and stability because of low shrinkage during firing. With this development, "refractory" technology was separated from the heavy clay industry, and special refractory brick works were established.

Historical Dates.

- Ca. 1820: The development of silica bricks for the iron and steel industry began, and fireclay brick was introduced in gas retorts
- Ca. 1860: The application of magnesite as a refractory material was proposed; the magnesite brick was developed about 20 years later in Austria
- Ca. 1870: Use of low-iron bauxite for manufacturing refractory crucibles
- Ca. 1880: Tar – dolomite products for Thomas steel converters and chrome ore bricks for the open-hearth furnace were developed
- 1892: Successful production of SiC in the United States
- 1914: Development of a plastic fireclay mix
- Ca. 1925: First manufacture of a hydraulic (cement) bonded mix (castable)
- 1928: Production of fused cast bricks began in the United States
- Ca. 1945: Earliest development of ceramic fibers and fiber products
- 1969: Initial development of low-cement castables in France
- Early 1980s: Introduction of magnesia–graphite bricks in the steel industry in Japan

The development of the refractory industry was similar to that of other industries. Initially there were only small workshops using manual methods, with process automation and scientific research arising much later. Since the early 1960s, a steadily increasing demand by the consumer industries has led to higher quality, tailor-made refractory products and cost-reducing application techniques.

3. General Classification and Nomenclature

Classifications of refractory products generally make reference only to characteristic limits for specific property values. The nomenclature and forms of designation are derived from features such as raw material base, manufacturing process, nature of bond, and typical application. The main classification criteria are:

1) Chemical and/or mineralogical constitution (see Table 1, ISO 1109-1975)
2) Total porosity
   Dense refractory products: < 45 vol %
   Insulating refractory products: > 45 vol %
3) Form of delivery
   Shaped products (bricks and shapes)
   Unshaped products (monolithics)
   Fibrous products (ceramic fiber products)
4) Type of bonding
   Bonding at < 150 °C; unfired products
   Ceramic bond (clay bond)
   Inorganic chemical bond
   Hydraulic bond
   Organic bond
   Bonding at 150 to 800 °C; thermally treated (tempered) products
   Inorganic chemical bond
   Hydraulic bond
   Bonding at > 800 °C
   Firing (ceramic bond)
   Fusion and solidification
5) Application field

Table 1. Classification of refractory products (ISO 1109 – 1975)

Products	Limiting content of principal constituent	Criteria of subdivision and general observations
High-alumina products Group 1	$Al_2O_3 \geq 56\,\%$	a complete designation of these products shall include an indication of either the raw material actually used or the mineralogical constitution of the final product. In the latter case, the method of ascertaining this constitution shall be stated
High-alumina products Group 2	$45\,\% \leq Al_2O_3 < 56\,\%$	
Fireclay products	$30\,\% \leq Al_2O_3 < 45\,\%$	
Low-alumina fireclay products [a]	$10\,\% \leq Al_2O_3 < 30\,\%$ $SiO_2 < 85\,\%$	
Siliceous products [a]	$85\,\% \leq SiO_2 < 93\,\%$	
Silica products	$SiO_2 \geq 93\,\%$	quality specifications according to use
Basic products		new subdivisions and new criteria of classification may become necessary
Magnesite (magnesia)	$MgO \geq 80\,\%$	products in which the principal constituent is magnesite (magnesia)
Magnesite- chrome (magnesia chrome)	$55\,\% \leq MgO < 80\,\%$	products in which the principal constituents are magnesite and chromite (magnesia)
Chrome-magnesite (chrome magnesia)	$25\,\% \leq MgO < 55\,\%$	products in which the principal constituents are chromite and magnesite (magnesia)
Chromite	$Cr_2O_3 \geq 25\,\%$ $MgO \leq 25\,\%$	products in which the principal constituent is chromite
Forsterite		products in which the principal constituent is forsterite
Dolomite (doloma)		products in which the principal constituent is dolomite (doloma)
Special products		products based on: carbon, graphite, zircon, zirconia, silicon carbide, carbides (other than silicon carbide), nitrides, borides, spinels (other than chromite)
		products based on several oxides (other than those of basic products)
		products based on pure oxides, including alumina, silica, magnesia, zirconia; products of high purity

[a] Products designated in certain countries by the name "semi-silica products" may belong either to the low-alumina fireclay class or to the siliceous products class.

4. Raw Materials [10], [16–19]

The refractories industry consumes a wide variety of raw materials, binders, and special additives.

Most of the raw materials are based on naturally occurring beneficated, upgraded, crushed minerals, usually acquired in captive production by the refractories manufacturer. Natural raw materials subject to large weight losses or volume changes when heated are prefired in rotating, shaft, or tunnel kilns before use (exception: quartz raw materials). The crushed, fired material (grog, grain) normally has a true porosity $< 10\,\text{vol}\,\%$. Natural raw materials that can be used without prefiring are listed in Table 2.

Several high-purity synthetic raw materials have become important in recent years because of the increasing demand for high-performance refractories. Synthetic raw materials are produced by special suppliers, and often supplied with defined particle-size distributions or as fine powders. To produce a grain from fine powders the synthetic materials are sintered in the form of briquettes at high temperature (up to 1800 °C or higher) or fused in electric arc furnaces and crushed. Fused grain materials have very low porosity ($< 3\,\text{vol}\,\%$) and large crystal sizes.

Porous raw materials and *ceramic fibers* are used for the production of thermal insulating refractories.

The grain or aggregate for a refractory is coarse and crystalline. Raw materials for the fines (i.e., for the matrix) are often chosen or prepared in less chemically stable forms (e.g., as "reactive calcines") and finely sized (sometimes $< 1\,\mu$m).

Refractory raw materials are subject to various types of quality control:

clays	**grain**
chemical analysis moisture content mineralogical composition refractoriness grain size distribution	
plasticity	grain density
deflocculant behavior	grain porosity
firing behavior (shrinkage, expansion)	crystallite size sintering behavior (fines)

In most cases, a prepared noncoherent mix of the refractory raw material (or several different

Table 2. Principal raw materials for refractory ceramics

Type	Main mineral phase(s) (minor phases)	Essential chemical components (ignited)	Remarks
Quartzite, silica sand	quartz (SiO_2)	$>97\,\%$ SiO_2, $<1.5\,\%$ Al_2O_3, low alkali content	used unfired; on firing, conversion to cristobalite and tridymite (increase in volume)
Fused silica	glass	$>99.8\,\%$ SiO_2	very low thermal expansion up to 1000 °C, above 1050 °C conversion to cristobalite
Loomy sand	quartz, clay minerals	$>83\,\%$ SiO_2, $4-12\,\%$ Al_2O_3	a clay-bonded sand (used as unshaped refractory material)
Refractory clays	kaolinite [$Al_2SiO_5(OH)_4$] and other clay minerals, quartz	$20-45\,\%$ Al_2O_3, $<3\,\%$ Fe_2O_3, $<3\,\%$ Na_2O+K_2O	special types: kaolin, flint clay, ball clay; on firing, conversion to mullite, cristobalite, and a glassy phase; loss on ignition $6-14\,\%$
Chamotte (burned clay)	mullite ($3\,Al_2O_3 \cdot 2\,SiO_2$), cristobalite ($SiO_2$), quartz, glassy phase	see above	firing temperature ca. 1200 – 1500 °C depending upon Al_2O_3 and alkali content, grain total porosity <10 vol %, special type: porous chamotte, bloated clay ($\sim$5 % Fe_2O_3)
Sillimanite, andalusite, kyanite	$Al_2O_3 \cdot SiO_2$ (different crystal structures)	$60-65\,\%$ Al_2O_3, low alkali content	above 1250 °C beginning of conversion to mullite, SiO_2, and small amount of glassy phase; high volume increase when firing kyanite; sillimanite and andalusite can be used unfired
Mullitized raw materials	mullite	$50-70\,\%$ Al_2O_3	fired mixtures of kaolinitic clay and refractory bauxite (Al-hydrate, $Al_2O_3 \cdot 2\,H_2O$)
Sintered mullite (synthetic)	$3\,Al_2O_3 \cdot 2\,SiO_2$	$72-75\,\%$ Al_2O_3	grain total porosity $\sim 10\,\%$, crystal size $10-150\,\mu m$ speciality: mullite hollow spheres [20]
Fused mullite	$2\,Al_2O_3 \cdot SiO_2$	$\sim 78\,\%$ Al_2O_3	grain total porosity $\sim 2\,\%$, crystal size $100-2000\,\mu m$
Sintered bauxite (refractory bauxite)	corundum (Al_2O_3)	$>85\,\%$ Al_2O_3, $<4\,\%$ TiO_2, $<2\,\%$ Fe_2O_3, low alkali content	producing countries: Guyana, China, Brazil; grain total porosity <10 vol %
Sintered corundum	corundum	$>99.5\,\%$ Al_2O_3, $<0.5\,\%$ Na_2O	grain total porosity $\sim 10\,\%$
Fused white corundum			grain total porosity $\sim 2\,\%$
Fused brown corundum	corundum	$94-97\,\%$ Al_2O_3, $3\,\%$ TiO_2	fused bauxite
Calcined aluminas	γ-Al_2O_3, corundum	$>99.5\,\%$ Al_2O_3, $<0.5\,\%$ Na_2O	fine powders ($<100\,\mu m$)
Corundum hollow spheres (2 – 4 mm diameter)	corundum	$>99.5\,\%$ Al_2O_3	fused Al_2O_3 sprayed by air stream (thermal insulating material)
Sintered magnesia (→ Magnesium Compounds, Chap. 4.)	periclase (MgO) dicalcium silicate, forsterite, calcium magnesium silicates	$85-99\,\%$ MgO, $0.1-3.5\,\%$ CaO, $0.1-3\,\%$ SiO_2, $0.1-8\,\%$ Fe_2O_3, $<0.3\,\%$ B_2O_3	firing of magnesite ($MgCO_3$) or $Mg(OH)_3$ from brines or seawater (→ Magnesium)
Fused magnesia		$97-99.8\,\%$ MgO$<2\,\%$ CaO,$<1\,\%$ SiO_2,$<0.2\,\%$ Fe_2O_3	grain total porosity $<8\,\%$, crystal size $60-200\,\mu m$ [21]grain total porosity $<2\,\%$, crystal size $400-3000\,\mu m$ [22]
Sintered dolomite	periclase (MgO), CaO	$56-62\,\%$ MgO, $36-40\,\%$ CaO, $<2\,\%$ SiO_2	firing of dolomite ($MgCO_3 \cdot CaCO_3$), prone to hydration
Sintered and fused CaO	CaO	$>98\,\%$ CaO	calcined calcite ($CaCO_3$)
Chrome ore (chromite)	$(FeO, MgO) \cdot (Cr_2O_3, Al_2O_3, Fe_2O_3)$ spinel	$10-20\,\%$ MgO, $32-50\,\%$ Cr_2O_3, $12-27\,\%$ Al_2O_3, $<6\,\%$ SiO_2	deposits: Turkey, Iran, Phillipines, South Africa
Magnesia – chrome sinters	periclase, spinel	normally up to $15\,\%$ Cr_2O_3	prereacted granulated mixtures of magnesite (magnesia) and chromite or dolomite
Magnesia – dolomite sinters	periclase, CaO	MgO and CaO in varying content	
Picochromite	spinel ($MgO \cdot Cr_2O_3$)	$19\,\%$ MgO, $79\,\%$ Cr_2O_3	fused mixture of magnesia and Cr_2O_3 powder

Table 2. (Continued)

Sintered and fused spinel	spinel ($MgO \cdot Al_2O_3$)	66 – 78 % Al_2O_3, 21 – 33 % MgO	synthetic material made from fine magnesia and alumina
Olivine, dunite	forsterite ($2\,MgO \cdot SiO_2$) – fayalite ($2\,FeO \cdot SiO_2$) – solid solution	40 – 50 % MgO, 35 – 45 % SiO_2, < 8 % Fe_2O_3	used unfired
Zirconium silicate	zircon ($ZrSiO_4$)	66 % $ZrO_2 + HfO_2$, 33 % SiO_2	extracted from sands (Australia), grain size < 0.3 mm, at temperatures above 1450 °C, decomposition to baddeleyite (ZrO_2) and SiO_2
Zirconia	baddeleyite (ZrO_2) (monocline)	> 99 % $ZrO_2 + HfO_2$	powders, chemically processed from zircon
Stabilized or partly stabilized ZrO_2	cubic/tetragonal phase of ZrO_2	> 94 % ZrO_2, 2 – 6 % CaO, MgO, Y_2O_3	stabilization because of irregular thermal expansion; ground, sintered, or fused material
Chromium oxide	escolaite (Cr_2O_3)	> 98 % Cr_2O_3	fine powder, produced chemically
Silicon carbide [23]	SiC (Si, C)	> 93 % SiC	produced from SiO_2 and C by the Acheson process
Natural graphite [24]	graphite (C), (clay minerals, mica, etc)	75 – 97 % various ash compositions	mainly two types : – flake graphite up to 5 cm crystal diameter – amorphous
7 Coke, anthracite, electrographite		75 – 99 % C	
Diatomite (moler)	opaline hydrous SiO_2, quartz (clay)	> 75 % SiO_2	fine porous siliceous rock (skeletons of aquatic plants)
Perlite	glass	65 – 80 % SiO_2, 12 – 16 % Al_2O_3, high flux content	prefired, hollow, spheric, glassy ingeneous rock
Vermiculite	magnesium, aluminum silicates (similar to mica)	45 % SiO_2, 31 % MgO, 13 % Al_2O_3, 7 % Fe_2O_3	exfoliated by heating, extremely low weight
Pyrophillite	$Al_2Si_4O_{10}(OH)_2$	20 – 30 % Al_2O_3, low alkali content	used unfired, loss on ignition 3 – 7 %; little expansion when heated; formation of mullite and SiO_2
Cordierite [25]	$2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$ (mullite)	31 % Al_2O_3, 53 % SiO_2, 10 % MgO	prefired grog from fine-grained magnesia and talc, low thermal expansion
Recycled refractory ceramics (from used refractory linings)		different compositions	recycled raw materials mainly from used, high-priced refractory products examples: fused mullite – zirconia grain from fused cast bricks, SiC- and zirconia-bearing materials
Ceramic fibers	glassy corundum/mullite (ZrO_2, Cr_2O_3)	system $Al_2O_3 - SiO_2$ 45 – 95 % Al_2O_3	two types available : glassy (amorphous) and polycrystalline
	ZrO_2	> 95 % ZrO_2	(see Section 7.3.2)

raw materials) is bonded by a suitable *binder* or binder combination (Table 3) to ensure sufficient strength at all steps during production or application of the refractory product. Even a small excess of binder may have a detrimental effect on hot strength and corrosion resistance because of its concentration in the matrix (fines).

Special *additives* (Table 4) are used to increase the workability and formability of a refractory mix or to modify refractory structure and the properties of the fired material.

Recycling of used refractory ceramics is complicated by the various contaminants introduced into refractory linings during use. Nevertheless, disposal problems and environmental considerations are expected to encourage efforts toward increased recycling.

5. Production

See also → Ceramics, General Survey.

Various methods are employed to produce refractory ceramics of different types:

1) Refractory products with large grain sizes, normally ≤ 6 mm (Section 5.1), in special cases ≤ 20 mm (pitch- and resin-bonded bricks, Section 7.1.6).

Table 3. Major binders for refractory mixes [6], [26] (often used in combination with water and as binder combinations)

Type of binder	Amount added	Remarks
Clays (plastic clays, ball clays)	$\leq 25\,\%$	strength after drying, ceramic bond at $> 1000\,^{\circ}C$ (formation of a melt, enhancing sintering)
High-alumina cements, calcium aluminate cements [27]	$\leq 25\,\%$	$50-80\,\%$ Al_2O_3, $19-38\,\%$ CaO, hydraulic bond, effectiveness between $20-600\,^{\circ}C$ (dehydration), $> 1000\,^{\circ}C$ ceramic bond
Monoaluminum phosphate (solution)	$\leq 5\,\%$ P_2O_5	hardening at about $200\,^{\circ}C$ by condensation reaction; at ca. $1300\,^{\circ}C$ formation of $AlPO_4$; $> 1500\,^{\circ}C$ onset of vaporization of P_2O_5
Inorganic phosphates, mainly sodium	$\leq 5\,\%$	used mainly in hot-repair mixes, hardening and adhesive strength by melting of the glassy phosphate
Alkali silicates $Na_2O(K_2O) \cdot x\,SiO_2 \cdot y\,H_2O$	$\leq 10\,\%$	normally used as solution, hardening at room temperature by CO_2 reaction or by hardener, thermosetting $> 150\,^{\circ}C$
Ethyl silicate $Si(C_2H_5O)_4$ [28]		used for slurry casting, gelation; curing at ca. $200\,^{\circ}C$
Magnesium sulfate ($MgSO_4 \cdot 7\,H_2O$ solution)	$\sim 5\,\%$	bond for unfired basic magnesitic refractories
Aluminum sulfate	$\sim 5\,\%$	mainly used in plastic mixes to increase drying strength (crystallization of aluminum sulfate)
Colloidal silica (silica sol)		binder mainly for ceramic fibers
Pitch, tar	$< 10\,\%$	organic bond, effectiveness at $20-450\,^{\circ}C$, coking at $600\,^{\circ}C$ (carbon bond)
Various synthetic resins [29]	$< 10\,\%$	modified phenolic resins in powder form or in solution of, e.g., formaldehyde; thermosetting resins (with hardener, hardening at ca. $200\,^{\circ}C$); $> 600\,^{\circ}C$: carbon bond
Variety of organic temporary binders and organometallic binders	$< 5\,\%$	to achieve sufficient strength after drying; burns out; organometallic binders: on heating, formation of sinteractive fine oxides
Boron oxide, other boron compounds	$< 10\,\%$	sintering aid (melt), especially for dry silica mixes
Frits, glass	$< 5\,\%$	mainly for unshaped refractories, low-melting flux- containing powders, to achieve ceramic bond $< 1000\,^{\circ}C$

Table 4. Special additives (normally $< 5\,\%$)

Type of additive	Purpose
Powders of nonoxides (C, Si_3N_4, SiC, BN, AlON, B_4C) and salts (e.g., $BaSO_4$)	to increase corrosion resistance, to reduce wettability by slags and metal melts; carbides also used as antioxidants
Reactive aluminas [10]	improvement of matrix (bond), to increase flowability of castables
Fine silica flour (silica fume) [30]	mainly used in unshaped refractories (castables) to increase flowability and hot strength (mullite formation)
Metal powders (Si, Al, Mg, or alloys)	antioxidants for carbon- containing refractories; to create a special nitridic or carbidic bond
Steel fibers [31]	reinforcement of unshaped refractories
Organic fibers [32]	to eliminate explosion hazard when heating castables
Organic grained materials	to create defined porosity or pore size
Various organic compounds	to increase formability of a mix; lubricants, surface-active substances (addition of $< 0.5\,\%$)
Ethylene glycol	antifreezing material for unshaped refractories

2) Special fine-grained refractory products (fine ceramics, Section 5.2).
3) Products formed via a melt (i.e., fused cast shapes, Section 7.1.9).
4) Ceramic fiber products (Section 7.3.2).

5.1. Production of Coarse-Grained Refractory Products

The production process includes the following steps:

1) Preparation
2) Shaping
3) Drying
4) Thermal treatment up to $800\,^{\circ}C$, or firing
5) Aftertreatment (if necessary)
6) Packing

A flow diagram for the production of dry-pressed fireclay bricks is shown in Figure 1. In order to achieve uniform products most manufacturing steps are now controlled electronically.

The fabrication of unshaped refractory products ends after mixing (Section 7.2), but plastic mixes can also be preformed into blocks using an

extruder. Other prefabricated shapes are manufactured from appropriate unshaped products.

Preparation. Various devices are used to comminute the raw materials; e.g., jaw crushers, impact crushers, ball mills, and vibratory mills (see also → Size Reduction). The crushed materials are then classified generally on vibrating screens.

These raw material components, a binder, additives, and water (up to 20 %) are fed into a mixer, yielding a moldable mix. Intermittent mixers are usually employed, but muller mixers and pug mills are also applicable. Mixing time, intensity, and sequence have a pronounced influence on the properties of the mix as well as on the product.

The properties of refractory ceramics can also be influenced by the grain-size distribution of the batch and grain sizes of the raw materials. Computational models have been used to establish graded grain sizings for dense packing [33]. Normal practice is to use three or four grain fractions (coarse, medium, fine, and finest). The fine (< 0.1 mm) and finest grains (required, for instance, in "binderless" batches) constitute the matrix of the fired product, which plays an especially important role in corrosion resistance. To increase thermal shock resistance the amount of coarse grain is increased at the expense of medium grain. Table 5 shows typical grain sizings for refractory bricks and castables.

Shaping. The preferred shaping method depends on the properties of the moldable mix (water content, plasticity), the required properties of the product, the number of pieces to be produced, and shape complexity. The following shaping methods are used:

1) Extrusion (pug mill) for plastic mixes (high clay, water content ≤ 8 %), and hydraulic, impact, friction, and rotary table presses (for "dry" mixes with 2 – 6 % water); pressures are normally 40 – 120 N/mm^2

Table 5. Grain sizings for typical refractory ceramics

Refractory	Grain-size fraction, %			Binder/water/additive content
	1 – 5 mm	0.1 – 1 mm	< 0.1 mm	
Silica brick	40	25	35	lime/2 % water/1.5 % sulfite lye
Fireclay brick (dry pressed)	35	25	40 (including clay)	15 % clay/5 % water
Magnesia brick	45	20	35 (10 % < 0.06 mm)	2 % water/sulfite lye
Conventional castable	25	30	35 (including cement)	15 % cement/9 % water (when used)
Low- cement castable	35	25	40 (10 % < 0.01 mm)	5 % cement/5 % fine oxide powder/5 % water (when used)

2) Vibration presses with low surcharge; mainly for prefabricated parts of unshaped refractories
3) Manual or mechanical ramming for complex shapes and small numbers of produced shapes
4) Isostatic pressing; mainly for fine grained high-quality products, with pressures $\leq 300\,\mathrm{N/mm^2}$
5) Slip casting; mainly for fine ceramics and special shapes, water content of slip 10 – 20 %

Drying. After shaping, bricks must generally be dried in drying chambers or tunnel dryers, taking advantage of waste heat from the firing kilns. Only completely dry shapes can be fired without danger of cracking. The drying process can take from several days to several weeks depending upon brick size and the drying sensitivity of the mix. Large shapes are dried under the controlled humidity of the drying air.

Thermal Treatment. Chemical (phosphate), organic, and hydraulic bonded shapes are often heated up to 600 °C to enhance chemical bonding (for higher strength) and to remove water of hydration or volatile organic components (e.g., in a pitch bond; tempering, coking).

Firing. During firing the characteristic ceramic microstructure develops as a result of reactions, recrystallization, and transformation or formation of a liquid phase or melt, respectively (at room temperature this phase consolidates to a glassy phase). With increasing firing temperature the porosity usually decreases, whereas both crystallite size and strength increase. These processes are generally associated with contraction or expansion, so the dimensions of a brick often change during firing, a factor that must be considered when molds are made. Indeed, the firing temperature may be limited by shrinkage or other deformation that would exceed the specified dimensional tolerances.

Various types of kilns (e.g., chamber, hood, and tunnel kilns) are used for firing, fueled by either gas or oil. Firing temperatures and energy requirements for various types of refractory brick types are as follows:

Fireclay bricks	1250 – 1500 °C	ca. 3500 kJ/kg
Silica bricks	1450 – 1500 °C	
High-alumina bricks	1500 – 1800 °C	≤ 1600 °C, ca. 6000 kJ/kg
Magnesia bricks	1500 – 1800 °C	≤ 1800 °C, ca. 10 000 kJ/kg

The firing and cooling curves, and sometimes also the kiln atmosphere (e.g., for magnesia chrome or chromia bricks) are adapted to suit the fired wares. Total firing time, including preheating and cooling, ranges from about three days (tunnel kilns) to about three weeks.

Aftertreatment. For special applications, fired bricks (especially larger shapes or blocks) may be sawn or ground as a way of achieving high dimensional accuracy.

In order to improve slag resistance, basic bricks for the steel industry are impregnated under vacuum with tar, pitch, or resin. Basic bricks can also be provided with steel cladding.

Production of Insulating Refractory Products and Other Porous Refractory Ceramics. To achieve a high porosity (> 45 vol %) four strategies are invoked:

1) Addition of burn-out or volatilizing substances to the mix (e.g., sawdust, coke, granulated plastic)

2) Use of porous raw materials such as diatomite, perlite, vermiculite, bloated clay, or hollow spheres (see Table 1)
3) Foam formation by gas-producing agents (metal powders)
4) Mixing with stabilized foams from colophonium soap or saponin

Most insulating bricks are pressed fireclay products produced with burn-out additives. Unshaped insulating refractory materials contain only porous raw materials.

Other porous refractory ceramics are the so-called porous plugs and ceramic filters (foams) for the steel industry. Unidirectional porosity is achieved by embedding burn-out plastic filaments. In the case of ceramic foam production, the pores of a burn-out sponge are covered with a ceramic suspension (slip).

5.2. Production of Fine-Grained Refractory Ceramics

Fine-grained refractory ceramics are used only to a minor extent, and for special purposes. These are mostly small items, often characterized by specific forms (e.g., plates, tubes, or crucibles), and they usually display little or negligible porosity. Only occasionally there is a demand for large blocks or other objects.

The starting materials for fine-grained ceramics are almost exclusively pure, finely-ground raw materials of the types used in the production of coarse-grained refractories, but other powdered oxides and even non-oxides may also be introduced. Most of the production processes are ones developed for the fine ceramic [34] and powder-metallurgy industries. Forming is normally accomplished by slip casting (→ Ceramics, General Survey) and isostatic pressing (→ Ceramics, General Survey). A freeze-molding process has also been developed [35]. Sintering is carried out at 1450 – 1900 °C. Shrinkage can be considerable (up to 25 % linear shrinkage); strict tolerances with regard to dimensions or surface quality are met by grinding. Dense, fine-grained refractory products are usually very sensitive to thermal shock.

5.3. Brick Dimensions and Dimensional Tolerances

Brick sizes for general use (rectangular and arch bricks, skew backs) are subject to international standards (ISO 5019/1 – 6). The standard rectangular brick sizes are:

1) 230 mm × 114 mm × 64 or 76 mm
2) 250 mm × 124 mm × 64 or 76 mm

Many other nonstandard shapes are employed for specific furnaces and applications (e.g., nozzles, blocks).

Dimensional tolerances are described in the 23rd Fédération Européenne des Fabricants de Produits Refractaires (PRE) Recommendation [36]. Depending on the nature of the refractory material, production method, and intended application, typical specifications are:

1) Dimensional tolerance max: 1 – 2.5 % (min. 2 – 3 mm)
2) Warpage max: 1.5 % (determined across the diagonal)
3) Taper max:
   ± 1 mm for radial height < 250 mm
   ± 2 mm for radial height > 250 mm Rectified (ground) bricks and blocks achieve a dimensional tolerance of 0.1 mm.

5.4. Packaging, Storage, and Storage Time

For purposes of storage and shipment, bricks, shapes, or bags of unshaped refractory materials are normally placed on standard wooden palettes and surrounded by a shrink-wrap film. In the case of heavy paletted shipments steel bands are used. Low-strength bricks (insulating bricks) are often packed in cardboard boxes. Unshaped refractory products are filled into paper bags lined with plastic film or into metallic drums. Delivery is sometimes made in big bags or by silo car.

Refractory ceramics generally must be stored in ventilated, covered, dry surroundings. Basic bricks and unshaped refractories are especially sensitive to moisture (hydration).

Unshaped cement or chemically bonded refractories have a limited storage life, usually 3 – 12 months.

5.5. Quality Assurance

Quality assurance systems are based on ISO 9000 – 9004, supplemented by an analysis of failure-mode effects as well as statistical process control. Quality assurance is integrated directly into every step in the manufacturing process from the delivery of raw materials to shipment of the finished product [37].

Sampling and acceptance testing are described in ISO 5022 (shaped products) and ISO 8656-1 (unshaped products). Inspection of attributes by nondestructive means (visual assessment) produces only a classification like "good" or "poor". More rigorous evaluation of variables normally requires destructive testing directed toward measurable properties. These tests are mainly chemical in nature and normally involve not more than three physical characteristics (open porosity, strength at room temperature, and hot strength or refractoriness under load).

6. General Composition, Properties, and Testing

The properties of refractory products are determined primarily by their chemical compositions, mineral compositions, and structure. Structure here refers to the type, quantity, size, form, and arrangement of phases in the substance involved. Refractory ceramics generally comprise three structural elements: coarse grain, binding matrix, and pores.

The binding matrix is of special importance with respect to refractoriness and corrosion resistance. It is usually associated with a higher degree of porosity than the grains, which have well-defined properties.

Fired bricks possess fixed, measurable properties. By contrast, unfired and unshaped ceramic products acquire their properties through use, in the course of which a temperature gradient is usually established. This temperature gradient gives rise to considerable property gradients between the hot face (sintered at the high-temperature end) and what is often a loose mass at the low-temperature face.

Properties are ascertained by applying various tests, most of which are standardized [36], [38]. Values depend on the test method employed and, in the case of unshaped products, also on the method of preparation of test pieces. Even standardized test methods are of limited value due to problems with reproducibility and comparability, a problem especially prevalent with destructive testing.

Table 6 summarizes important property tests conducted on refractory materials.

Figure 2. Porosity effects on the properties of refractory ceramics
a) Corrosion; b) Thermal shock resistance; c) Thermal expansion; d) Bulk density; e) Strength (fine ceramics); f) Thermal conductivity; g) Modulus of elasticity; h) Cold compressive strength (coarse refractories)

Chemical and mineralogical composition forms the basis for both classification and service behavior (e.g., with respect to corrosion resistance). In moderately pure materials the chemical composition is of secondary importance with respect to technological properties. However, as quality requirements become more

Table 6. Tested characteristics of refractory ceramics

Chemical, mineralogical	Texture	Cold mechanical	Hot mechanical	Thermophysical	Thermochemical

[a] For statistical quality control. [b] Additional information for data sheets. [c] [41]. [d] [42]. [e] [43].

stringent even small amounts of foreign oxides can exert a considerable influence.

Porosity has a considerable effect on properties (Fig. 2). It is difficult to optimize a refractory material with respect to porosity (e.g., for increased resistance to corrosion or thermal shock). The different types of porosity and pores are illustrated in Figure 3, together with associated test methods. The proportion of closed pores in bricks with porosity exceeding 15 % is normally small (< ca. 3 %). Relationships between porosity and other properties can be established most accurately by determining pore size distribution [39], [40] and gas permeability.

Bulk density characterizes the weight of a product per unit volume, including all pores. It is needed to calculate porosity, refractory requirement, weight of a refractory lining, stored heat, etc. Bulk density is influenced by the material density (weight per unit volume, excluding pores), which is a constant for each material, and porosity. Densities for refractory ceramics range between 2.2 g/cm^3 (fused silica) and 5.9 g/cm^3 (ZrO_2).

Cold Mechanical Properties. Cold crushing and modulus of rupture (bending) tests provide information about the structure and structural uniformity of a ceramic and assist in statistical quality control. This information is of little value in assessing high-temperature behavior, however. Strength is dependent on the shape of a sample and the conditions of testing. The distribution of strength values within a brick or batch is relatively wide. Resistance to abrasion is determined by abrasive or jet wear, but can be estimated from the above strengths.

Nondestructive Testing [44–47]. There is an increasing tendency to use nondestructive

Figure 3. Types of porosities and pores in refractory materials and test methods

testing, particularly for large refractory ceramic objects with a high unit price. Ultrasonic testing is the most common nondestructive procedure for checking the strength, porosity, and integrity of refractory materials. Other methods include resonant frequency, rebound hammer, and, for crack or void locations, X-ray techniques. The interpretation of nondestructive test data is complicated by the fact that results are often not closely related to values obtained from conventional destructive testing.

Refractoriness (see also Chap. 1). For bricks belonging to the silica – firebrick – corundum series, the cone equivalent serves as a measure of the content of fluxing agent. Refractoriness is also determined, however, by ceramic structure, distribution of the fluxing agent, and viscosity of the resulting melt. Cone equivalents are of little value for basic and other highly refractory products.

Most refractory products lack a defined melting point, instead displaying a more or less broad softening interval.

Thermal expansion is a material constant determined primarily by the basic component of the ceramic (e.g., SiO_2, MgO). With the exception of silica and zirconium oxide (Fig. 13) containing products, fired ceramic materials have smooth thermal expansion curves [48] (Fig. 4). During initial heating, unfired bricks and unshaped refractories show overlap between reversible thermal expansion and irreversible expansion/shrinkage effects, which are influenced even by small loads. Reversible and permanent changes in length are of importance for construction of a refractory lining, e.g., when measuring joints. Because thermal expansion cannot be suppressed even with high loads some fraction (usually 0.5 – 0.8) of the laboratory expansion value is used for dimensioning joint thickness; the correct choice depends on furnace construction and operating conditions.

Reheat Change. Heating to high temperatures and subsequent cooling often causes a permanent, time-dependent change in dimensions. If a refractory lining shows substantial shrinkage, joints or cracks may form. The opposite case, after-expansion, is also dangerous, because the resulting pressure may destroy the refractory lining. Dense bricks should not show more than 1 – 1.5 % linear shrinkage at maximum service

Figure 4. Thermal expansion curves of fired refractory materials
$*$ $MgO \cdot A_2O_3$, $MgO \cdot Cr_2O_3$, chrome ore. $**$ After expansion when residual quartz is present.

temperature. The appropriate tests are described in ISO 2477 (insulating bricks) and ISO 2478 (dense bricks).

The classification-temperature criterion for insulating and unshaped refractory products is limited linear heat shrinkage at a defined temperature and holding time (5 – 24 h). The following shrinkage limits apply:

Insulating fire bricks	max. 2 %	
Ceramic fiber products	max. 4 %	
Castables	max. 2 %	drying and firing shrinkage
Ramming mixes	max. 2 %	drying and firing shrinkage
Moldable mixes	max. 3 %	drying and firing shrinkage

Refractoriness Under Load. Determination of the refractoriness under load (differential, with rising temperature; ISO 1893, DIN 51 053, part 1) is a characteristic test for refractory products. Samples are normally cylinders (height 50 mm, diameter 50 mm) with an internal axial bore (diameter 12.5 mm). These are heated in air under a load of 0.2 N/mm^2 at a rate of 5 °C/min until they become soft. Characteristic temperatures (e.g., T_{05} and T_{10}) are read from a height- change – temperature curve (see Fig. 5). Some products display a broad softening range (e.g., fireclay bricks), while others show a sudden collapse (e.g., silica and magnesia bricks).

The ISO 1893 differential method establishes an actual change in sample length, and was developed from the refractoriness-underload method described in DIN 51 064. The main differences between the two methods are that in DIN 51 064 the measured expansion includes the expansion of the loading columns (carbon), and the test takes place in a carbon resistance furnace (i.e., in a reducing atmosphere). DIN

51 064 characterizes a sample by two parameters, t_a and t_e, where t_a is the temperature at which the sample is compressed by 0.6 %, and t_e that at which it is compressed by 20 %.

Figure 5. Refractoriness under load curve

The ISO differential method generally produces substantially lower test values than DIN 51 064. Materials that are sensitive to redox conditions (e.g., iron-rich magnesia) show particularly drastic deviations. For example:

	Differential method ISO 1893 T_{05}	DIN 51 064 method t_a
Fireclay brick	1250 °C	1350 °C
High-quality fireclay	1440 °C	1490 °C
Bauxite brick	1450 °C	1550 °C
Iron-rich magnesia brick	1500 °C	1700 °C
Low-iron magnesia brick	1680 °C	1700 °C

Softening behavior under pressure is influenced by several factors: the type of refractory material, its mineralogical and pore structure, and the quantity and viscosity of the melts formed at high temperature. Compression softening behavior improves with increasing firing temperature.

Creep in Compression. Refractory products are often exposed to high temperature and pressure for extended periods of time (e.g., the checkerwork of regenerators). This results in slow shrinkage and creep processes that influence refractory lining lifetimes. Such behavior is characterized by the creep test (ISO 3187), which is performed at constant temperature and pressure. The test is carried out as described in ISO 1893, but once the test temperature is attained it is maintained for 25 h. Loading conditions can be selected to correspond to those expected during service. The result can be read from the "creep curve", for example as percent shrinkage after 25 h (Fig. 6). Creep curves for various refractory materials are shown in Figure 7.

Behavior over longer time periods can be estimated by extrapolation. For rough calculations, the increase in compression creep can be assumed to be proportional to the applied compression load. A temperature increase of ca. 100 °C increases creep by a factor of 5 – 6 [49].

For a brick to show a low degree of long-term creep it should have a high-fired structure, a low porosity, and a low flux content or a low proportion of liquid phase at service temperature.

Hot Mechanical Properties. Thermomechanical behavior is important in the application of a refractory product, and it can be characterized by high-temperature strength testing. Strength is a complex parameter that depends on the structure, quantity, and properties of the glassy phase. The temperature dependence of thermal behavior is a function of the type of loading involved (e.g., bending, compression, tension, or torsion).

One common measure of thermomechanical character is the hot modulus of rupture test (ISO 5013), which is frequently incorporated into the quality control of refractory products. In polycrystalline bricks with low amounts of glassy phase (e.g., corundum or magnesia), strength tends to decrease gradually with increasing temperature. However, if a liquid phase is formed the hot strength can decrease suddenly. In refractory products with a high content of glassy phase (e.g., fireclay brick) a hot-strength maximum occurs at the temperature where the glassy phase starts to soften (high viscosity). Such maxima can also occur if stresses arise in the structure (e.g., in cases with strongly differing expansions of the different refractory components, such as magnesia and chrome ore in magnesia chrome bricks, or cristobalite in fireclay bricks (Fig. 8).

Thermal Conductivity, Specific Heat, and Emission.

Thermal conductivity values are used primarily to calculate the temperature distribution in a refractory wall and the heat loss of a furnace. In some cases products with high conductivity are used to keep the temperature of the hot

Figure 6. Creep curve

side of the lining low, thereby reducing wear. The thermal conductivity of a refractory material depends on its chemical and mineralogical composition, and especially on its porosity and pore size distribution. The atmosphere is also of great importance, most notably in the case of porous products [50], [51].

The thermal conductivity of refractory products ranges from ca. 0.05 (ceramic fibers) to $100\,\mathrm{W\,m^{-1}\,K^{-1}}$ (graphite) [48] (Fig. 9). Monocrystalline products like corundum brick show a considerable decrease in thermal conductivity with increasing temperature until such time as the heat transfer by radiation (above ca. 800 °C) again increases total conductivity. Products with a complex structure (e.g., silica brick, which has several crystalline phases, and products with a high content of "amorphous" phases) normally have lower thermal conductivities than monocrystalline materials. In this case conductivity increases slowly with temperature.

There are two standard methods for measuring thermal conductivity: the hot-wire test (ISO 8894, ASTM C 1113) and the calorimeter method (ASTM C 201). Values obtained by the two methods may differ by up to 25 %. The method used should therefore be specified whenever thermal conductivity values are given. This is particularly important for unshaped products; in such cases, special attention must also be given to pretreatment of the sample [52].

Specific heat [48] is used to calculate the heat stored by a lining, and for determining the temperature diffusivity that results from thermal conductivity in order to calculate nonstationary temperature fields in, for example, regenerators. The specific heat for conventional refractory products is ca. $1\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$.

The thermal emission of a refractory construction material depends on the type of material and the nature of the surface. Refractory products can be regarded as gray-body radiators, with emissions 50 – 85 % as great as black-body radiators [53], [54].

Electrical Resistance [48]. The electrical resistance of a refractory material is important with respect to the insulation and operation of electrical furnaces. Conventional refractory ceramics display very high electrical resistance at room temperature ($> 10^5\,\Omega\cdot\mathrm{m}$), but this decreases with increasing temperature, reaching values like $1\,\Omega\cdot\mathrm{m}$ at 1400 °C. Even low concen-

trations of foreign components can substantially reduce electrical resistance.

Elasticity and Stress – Strain Behavior. A *modulus of elasticity* value is determined in order to estimate the critical stress on a refractory material brought about by mechanical and thermal loading. The *static* modulus of elasticity is established by measuring deformation under compression, bending, and tension. For simplicity, *dynamic* elasticity is determined by means of ultrasonic velocity or resonance frequency. Values obtained by different methods can differ substantially, and they also depend on the type and structure of the refractory material under investigation (Table 7) [55]. The dynamic modulus is higher than the static modulus. Refractory bricks often show strictly elastic behavior only within a narrow deformation range. Increasing stress and temperature leads to irreversible deviations from linearity. This is a consequence of deformations caused by mechanical or creep factors at higher temperatures. Irreversible changes are an indirect result of the porous, inhomogeneous textures of refractory materials. Their structure – a combination of relatively solid, less deformable, coarse and medium particles together with a less solid and more deformable matrix – is particularly important in this respect. The temperature dependence of stress – strain curves for a refractory material provides an indication of the elasticity of the microstructure (relaxation) and the onset of plastic deformation.

Thermal Shock Resistance. Thermal shock resistance is an important property that describes the behavior of a material during a more or less rapid change in temperature. Cracks can lead to considerable wear due to spalling, and they also increase susceptibility to corrosion. The test procedures are quite diverse (water or air quenching, dipping in metal melts, flame impingement tests, cycling between two temperatures, etc.). Thermal shock resistance is highly dependent on sample shape and the test conditions. Densification, uptake of foreign material, and the formation of zones of differing thermal expansion during refractory product use can also lead to substantial changes in thermal shock resistance. Thus, only a test procedure adapted to suit specific service conditions has any chance of success. Another way of circumventing the difficulties with thermal shock tests is to invoke thermal shock parameters. These represent an attempt to classify materials in terms of other properties (e.g., strength, modulus of elasticity, thermal expansion, thermal conductivity, work of fracture, and fracture toughness) [56], [57]. Two important parameters have been defined to

Figure 9. Thermal conductivity of refractory products

assess the thermal shock resistance of refractories:

$$R'''' = \frac{WE}{S^2}$$

(situation involving a fracture of a catastrophic nature)

$$R_{\mathrm{ST}} = \left[\frac{W}{\alpha^2 \cdot E}\right]^{0.5}$$

(situation in which crack propagation is stable or quasi-stable)

where W = work of fracture; E = modulus of elasticity; S = modulus of rupture; and α = thermal expansion coefficient.

Corrosion Resistance. The corrosion resistance of a refractory product is influenced primarily by the chemical compositions of the corrosive agents and the refractory material. Porosity, pore-size distribution, and mineral structure

of the refractory material determine the reaction kinetics. Corrosion is greatly affected by specific operating conditions (furnace atmosphere, temperature, temperature gradient in the lining, crack formation due to additional temperature changes, static or dynamic action of the corrosive media), so conclusions drawn from laboratory slagging experiments are of limited value unless these have been carefully related to real operational conditions.

The diverse character of corrosive attack on refractory materials is reflected in the numerous corrosion tests proposed [58], [59].

Refractory products are subject to three main types of corrosive stress:

1) Effects of the atmosphere and changes in the atmosphere
2) Attack by vapors, flue dusts, and condensates
3) Attack by slag and other fluid media

Effects of the Atmosphere and Changes in the Atmosphere. A change in the valency of components of the refractory material (e.g., iron oxide), as well as absorption of such substances as V_2O_5, can lead to a loosening of brick structure. Even small amounts of metallic iron or iron oxide present in e.g., fireclay or bauxite products can lead to the catalytic deposition of carbon from carbon monoxide (500 – 700 °C) and methane (> 900 °C). The resulting crystallization pressure can destroy the brick structure (CO disintegration). Vaporization processes are accelerated under a reducing atmosphere.

Attack by Vapors, Flue Dusts, and Condensates. Corrosive substances are brought in contact with refractory construction materials by the flow of combustion gases. Components present in certain temperature zones react with the refractory material, especially in their condensed states. A typical example is found in the middle checker layers in glass-furnace regenerators. Corrosion involves wetting, diffusion, impregnation, the formation of dripping melts, and periodic melting and solidification of infiltrated melts. Very great damage is caused by alkali bursting of fireclay and high-alumina bricks, a consequence of the substantial volume increase accompanying formation of nepheline ($Na_2O \cdot Al_2O_3 \cdot 2\,SiO_2$) or kaliophilite ($K_2O \cdot Al_2O_3 \cdot 2\,SiO_2$).

Table 7. Strength and elasticity properties of refractory bricks

Attack by Slag, Melts, and Other Fluid Media. Corrosive processes caused by slags and melts are a consequence of several phenomena (wetting, dissolution, diffusion, free and forced convection) that occur at the same time and place and often interact in a complementary way. Premature wear develops at the three-phase boundary attacking melt – refractory material – atmosphere (*melt line, flux line*) [60].

The intensity of the slagging processes in porous materials exposed to melts is primarily determined by interface properties (i.e., wettability and viscosity) of the attacking molten medium or reaction products. The formation of highly viscous reaction melts, deposits, or protective layers retards the slagging process.

Crucible tests (DIN 51 069) are usually performed in cavities prepared in cubes of the test material. The corrosive material (e.g., glass, slag, or a salt) is placed in the prepared cavity and the crucible is then heated. This test provides only a rough classification of materials.

Button and Drip Tests. The corrosive substance is placed as a pellet or dropped onto the test material. Wettability can be assessed using the sessile drop method (hot stage microscope).

Immersion Tests. The rod-immersion method has achieved considerable importance for testing the attack of melts on refractory materials. Compared to the crucible test this provides a larger quantity of attacking medium relative to the sample surface. In addition, rods or disks of test material can be rotated (dynamic test). Hanging samples can also be used to test corrosion in an atmosphere. This method is employed to test the behavior of refractory bricks on exposure to vapor from alkaline compounds located at the base of the crucible.

Semi-Industrial Corrosion Tests. These tests are somewhat extravagant in terms of time and equipment, and are a response to the demand for a test procedure that provides assessments as equivalent as possible to actual operating conditions. This in turn implies that each procedure must be adapted to a specific application. Special emphasis is placed on the testing of large samples (e.g., a brickwork), which allows one also to test the joining materials. Joints constitute a vulnerable area in a brick lining. For the iron and steel industry, the combined effect of metal and slag is tested. Thermal shock can also be superimposed on the slagging process to obtain a comprehensive picture of wear processes.

The following semi-industrial test procedures are most common:

1) Rotary furnace test
2) Vertical-type rotary furnace tests
3) Chamber slagging furnaces for blowing in or on corroding vapors, etc.
4) Induction and arc furnaces (laboratory scale)

7. Types of Refractory Ceramics

7.1. Dense, Shaped Refractory Products

Characteristics of selected types of conventional refractory bricks are summarized in Tables 8 and 9.

7.1.1. Silica Bricks and Fused-Silica Ceramics

Silica bricks (> 93 % SiO_2) [61–63] consist mainly of silicon dioxide (SiO_2), generally described as silica. Silica occurs in a variety of crystalline modifications (e.g., quartz, cristobalite, tridymite), each with a high- and low-temperature modification, and also as an undercooled melt called *fused silica.* The crystal structures of the SiO_2 modifications differ widely, so distinct density (volume) changes and steps in the thermal expansion are seen during transformation (Fig. 10). This is of great importance during heating and cooling (i.e., during firing and use of silica refractories).

The raw materials for silica bricks are naturally occurring quartzite and other quartz materials with low Al_2O_3 and alkali oxide content. The grained material is normally bonded with about 2 – 3 % slaked lime and some sulfite lye solution as a temporary binder. Dense silica bricks are produced by adding Si- containing powders (e.g., Si_3N_4), which decompose on firing to a dense tridymite-rich SiO_2 matrix [62], [64].

Figure 10. SiO_2 modifications and their transformations

Fired silica bricks contain cristobalite, tridymite, perhaps some residual quartz (usually $< 6\,\%$), some wollastonite ($CaSiO_3$), and about $2-10\,\%$ glassy phase. Silica bricks are characterized by very good thermal shock resistance above 600 °C and high-temperature load-bearing capacity up to about 1600 °C.

Applications: coke ovens, hot blast stoves, glass melting furnaces (crowns), and furnaces for the ceramics industry.

Silica bricks in the applications cited usually show no deformation or critical wear. Acquired impurities migrate with melts from the bricks themselves deep into the cold part of the lining, leading to a zoned texture that is prone to thermal shock. Condensations of alkali (occurring at temperatures $< 1400\,°C$) lead to a melting and dripping of the brick surface.

Fused silica products are fabricated as fused blocks (manufactured with a special sink fuse method) or in special shapes starting from crushed fused grain, formed (often by slip casting [65]) and fired at about 1050 °C. A characteristic feature of fused silica is its very low thermal expansion (i.e., high thermal shock resistance). At about 1150 °C cristobalite crystallizes without any large volume change. This crystallized material is sensitive to cooling below 300 °C (like silica bricks).

Applications: mainly in the glass industry, for hot repairs; submerged nozzles and shrouds for the casting of steel; foundries.

7.1.2. Fireclay and High-Alumina Bricks

These refractory products belong to the system $SiO_2-Al_2O_3$ (Fig. 11) [66]. Only three phases exist in this system: crystalline SiO_2 modifications, corundum (α-Al_2O_3), and mullite. The composition of the mullite ranges from $3\,Al_2O_3 \cdot 2\,SiO_2$ with about 72 % Al_2O_3 (formed on sintering above about 1000 °C) to $2\,Al_2O_3 \cdot SiO_2$ with about 78 % Al_2O_3 (crystallizes from melt). Even small amounts of impurities or flux (always present in industrial refractories) may drastically change the phase relationships and the stability temperatures of the phases. The influence of impurities generally present in the raw materials on the formation temperature for the first melt (eutectic temperature) is as follows:

Pure system	1590 °C	FeO	1250 °C
TiO_2	1480 °C	Na_2O	1050 °C
MgO	1425 °C	K_2O	985 °C
CaO	1345 °C		

The flux content (especially $Na_2O + K_2O$) determines the extent of glassy phase or viscous melt at high temperature, and thus the refractoriness. Fe_2O_3 and TiO_2 are partially incorporated into the mullite lattice and do not completely act as flux. The significance of the Al_2O_3 content is overshadowed by the influence of the flux content.

The morphology of mullite crystals may vary considerably depending on the type and composition of the raw materials, the formation conditions during firing, and subsequent thermal treatment. Mullite shapes range from fineneedled crystals formed at low temperature in the presence of a melt to coarse crystals in materials with low flux content, fired at high temperatures, or in fused mullite. The shape of the mullite crystals and their arrangement in the texture of the brick (e.g., "mullite felt") has a pronounced influence on the properties of fireclay and high-alumina bricks, especially on hot strength.

An overview of refractoriness and maximum application temperatures for fireclay and high-alumina bricks is given in Figure 12. Refractoriness in the field of fireclay refractories falls considerably below the liquidus line of the pure system $SiO_2-Al_2O_3$ because of a high content of alkali oxides and alkaline earths. Maximum application temperatures are distinctly lower due to time-dependent shrinkage or creep, which significantly affects the life of a refractory lining. It is also necessary to distinguish between application under a thermal gradient (as in a refractory wall) and under quasi-isothermal conditions (checkers in regenerators). The broad range of maximum application temperatures for high-alumina bricks shows clearly the influence of the diverse chemical and mineralogical compositions of these bricks.

Fireclay Bricks. According to ISO 1109, fireclay bricks have an Al_2O_3 content of $10-45\,\%$. They are manufactured from chamotte and bonding- clay mixtures. The limit of 45 % Al_2O_3 represents the maximum Al_2O_3

Figure 11. Phase diagram $SiO_2 - Al_2O_3$

content of the clay mineral with the highest alumina content (i.e., ignited kaolinite). The amounts of bonding clay and added water vary, a factor that largely determines both the subsequent forming process (plastic, semidry, dry shaping) and the properties of the resulting fired bricks. Low-alumina or siliceous fireclay bricks may contain as additives granular SiO_2 raw materials. Variation of the clays, grogs, and grain sizes permits the production of numerous brick types (see [67]). Fireclay bricks contain up to ca. 3 % Fe_2O_3 (for low-iron bricks, < 1 %), ≤ 3 % TiO_2, < 1 % CaO + MgO, and alkali oxides, mainly K_2O (≤ 3.5 %) and Na_2O (usually < 0.25 %). High-quality bricks include < 0.5 % $Na_2O + K_2O$.

Mullite, cristobalite, and/or quartz and a glassy phase (composition: ca. 80 % SiO_2, 10 % Al_2O_3, the rest fluxes, mainly alkalies) are the usual components of fireclay bricks. The mullite content is generally proportional to the Al_2O_3 content of the bricks. The amount of cristobalite (0 – 25 %) and of the glassy phase (20 – 60 %) depends largely on the content of alkali oxides, which can be deduced from the phase diagram $Al_2O_3 - SiO_2 - K_2O$ [68]. With rising temperature, cristobalite dissolves in the glassy phase, increasing the amount of melt. On cooling, the cristobalite again crystallizes to a greater or lesser extent from the melt. The amount of residual quartz depends on the firing temperature and the grain size of the quartz.

The resulting highly viscous melt enhances both sintering and densification of the brick texture on firing. A high firing temperature is necessary with a low alkali content to produce a low-porosity brick. Otherwise the glassy phase begins to soften at about 950 °C, imparting a wide softening range under load.

Attack by slag on fireclay bricks normally occurs in relatively small reaction zones; wear progresses by erosion of the resulting highly viscosity reaction zone. In contact with glass melts, alkali migrates into the brick texture and the bricks are slowly dissolved in the glass melt. Other forms of damage include alkali bursting (for bricks with > ca. 35 % Al_2O_3), CO disintegration, and thermal spalling (dense bricks).

Main applications: general furnace construction, blast furnaces and hot-blast stoves, foundries, furnaces for the nonferrous-metal in-

Figure 12. Refractoriness, refractoriness under load, and maximum application temperature of fireclay and high-alumina bricks

dustry, coke ovens, glass industry, cement industry.

High-Alumina Bricks [69]. Bricks with $> 45\,\%$ Al_2O_3 are required for increased thermal and chemical stresses. These are produced from various high-alumina raw materials (sillimanite group, mullitized materials, sintered and fused mullite and corundum, sintered bauxite; see Table 2), alone, in combination, or together with other raw material types, mainly chamotte. The nomenclature applied to the products depends on the primary high-alumina raw material.

A small amount of clay ($< 15\,\%$) is normally used to produce ceramic-bonded fired bricks. Use of a mixture of clay and fine alumina leads to a mullite-bonded corundum brick. A chemical bond on an aluminum phosphate base has also proven successful. This brick type is supplied either fired (1000 – 1500 °C) or heat-treated (150 – 800 °C). The chemical bond gives the brick greater resistance to attacking melts, slag, and alkali oxides. A pitch or resin bond is used for applications in the steel industry. Coking at about 300 °C causes a slag-rejecting carbon bond to develop. In special cases fired bricks are pitch- or resin-impregnated.

Addition to corundum bricks of Cr_2O_3 powder (5 – 15 %), either alone or in combination with zirconium silicate, leads to a highly corrosion-resistant corundum chrome brick [70], [71].

The chemical and mineralogical compositions of high-alumina bricks vary over wide ranges because firing of the bricks normally fails to produce phase equilibrium, and significant changes may occur in the properties of the bricks in service [72]. Bauxite bricks, which constitute the majority of high-alumina bricks, show more or less after-expansion in service caused by reactions between clay bond and corundum and resulting in mullitization [73]. Compared with

fireclay refractories, the alkali oxide content and the extent of glassy phase is low (< 20 %). The main mineralogical components are corundum and mullite. Sillimanite and andalusite bricks normally contain residual amounts of these minerals.

Properties of the different types of high-alumina bricks (for applications in the iron and steel industry) are compiled in [74].

The corrosion resistance of such bricks to glass, slag, and iron and steel melts is good. They are prone to alkali attack: high-alumina bricks with low Al_2O_3 content react to produce low-melting alkali aluminum silicate phases or glasses. With higher alumina content alkali bursting occurs (due to crystallization of, for example, nepheline), as does the formation of β-Al_2O_3.

Main applications: iron and steel industry, nonferrous industry, glass and cement industry, ceramic industry (also as high temperature kiln furniture).

7.1.3. Basic Bricks [75] (→ Magnesium Compounds, Chap. 4.3.1.)

Basic bricks belong mainly to the system MgO – CaO and consist of magnesia (periclase), dolomite, and CaO. Combinations with chrome ore, spinel ($MgO \cdot Al_2O_3$), and carbon (graphite) (see Section. 7.1.6) are also found. Forsterite, chrome ore, and spinel bricks are included as well, since these bricks are often used in place of or in contact with magnesia bricks. An overview is provided in Table 10. The discussion that follows is based on the classification scheme used in [76].

Magnesia Bricks. According to ISO 1109, magnesia bricks contain at least 80 % MgO. A variety of magnesia raw materials has been used to manufacture magnesia and magnesia-containing products (i.e., natural magnesite sinters, seawater magnesia, fused magnesia with various chemical and mineralogical compositions; → Magnesium Compounds, Chap. 4.). Magnesia contains varying amounts of Fe_2O_3 (< 8 %), Al_2O_3 (< 0.3 %), CaO (< 4 %), SiO_2 (< 4 %), and B_2O_3 (< 0.2 %). Beside the main mineralogical component periclase, silicates and ferrites occur as secondary components. The CaO/SiO_2 ratio (→ Magnesium Compounds) and the B_2O_3 content (formation of low melting components) are especially important in determining the mineral compositions and properties (hot strength, corrosion resistance) of magnesia bricks. Monticellite ($CaO \cdot MgO \cdot SiO_2$, CMS) with a CaO/SiO_2 mass ratio of 0.94, has the lowest melting point (1495 °C) of the silicates.

High-performance bricks are highly fired, have a low iron content (< 1.5 % Fe_2O_3), and contain a dicalcium silicate (short formula: C_2S, *mp* 2130 °C) or forsterite (short formula: M_2S, *mp* 1890 °C) bond. These bricks show first subsidence at temperatures ≥ 1600 °C (see Table 9). Magnesia bricks display high thermal expansion and are prone to thermal shock and thermally induced stress in furnace linings. Thermal shock resistance can be increased by a coarse grain distribution or the addition of Al_2O_3 (spinel formation on firing, microcrack formation) or chrome ore (texture elasticity). Special products include magnesia – forsterite (olivine) bricks and zircon- or zirconia- containing magnesia bricks.

High refractoriness, good resistance to attack by basic slags, and alkali resistance characterize magnesia refractories. Slagging causes diffusion and migration of silicate or ferritic melts deep into the brick, producing a zoned structure prone to peeling (structural spalling). A pitch, resin, or carbon bond reduces the infiltration of metal and slags under reducing-atmosphere service conditions. Magnesia bricks are sensitive to hydration (humid atmosphere between 40 – 120 °C), SO_3 (magnesium sulfate formation), and SiO_2 attack (forsterite bursting). Excessive growth of magnesia crystals during service, promoted by acquired impurities and high temperature, can also loosen brick texture.

Applications: steel melting and refining furnaces and vessels, regenerators for glass melting furnaces, cement and lime furnaces.

Dolomite Bricks. These consist of sintered dolomite (doloma), the main components of which are evenly distributed CaO and MgO. The principal impurities are calcium compounds like dicalcium ferrite (C_2F), brownmillerite (C_4AF), tricalcium aluminate (C_3A), tricalcium silicate (C_3S), and dicalcium silicate (C_2S). The SiO_2 content should be < 1 % to avoid excessive

Table 10. Classification and types of basic bricks

Brick type	Groups MgO content, %	Remarks
Magnesia	85 – 98	including pitch- or resin-bonded untempered and tempered bricks (carbon content after coking $< 7\,\%$)
Magnesia – dolomite	50 – 80	
Dolomite	30, 40	
Magnesia – carbon,	30 – 70,	addition of natural graphite
Magnesia – dolomite – carbon,	$C \geq 7\,\%$,	pitch- or resin-bonded untempered and tempered bricks
Dolomite – carbon	(up to 25 %)	with or without antioxidants
Magnesia – chrome	30 – 80	subgroups: direct bonded, rebonded, and chemically bonded bricks
Chrome ore	< 30	
Magnesia – magnesium aluminum spinel	60 – 80	
Spinel		$MgO \cdot Al_2O_3$, $MgO \cdot Cr_2O_3$
Forsterite		fired and unfired bricks
CaO	$CaO > 70$	

C_2S, which tends to cause "dusting" because of changes in the modification. The addition of 1 – 3 % ZrO_2 increases thermal shock resistance [77].

Their free-lime content makes these products susceptible to hydration. For this reason, manufacture, transport, storage (packed in shrink foils), and installation require virtually moisture-free environments and early use or heating. Hydration resistance is increased by pitch or resin bonding and tempering or tar dipping and impregnation of the fired bricks.

Dolomite bricks are sensitive to attack by iron-rich and SiO_2-rich slags. The periclase component is more resistant than the CaO component. Fluid melts are formed with slags rich in FeO. MgO absorbs the FeO in a solid solution.

Applications: mainly converters and ladles for the steel industry (pitch- or resin-bonded, tempered bricks) and the cement and lime industry (fired carbon-free bricks) in competition with magnesia bricks.

Magnesia – dolomite bricks contain mixtures of sintered (sometimes fused) dolomite and magnesia as a way of combining for special purposes (steel converters and ladles) the individual properties of MgO and CaO.

Calcium Oxide Refractories. Despite good corrosion resistance and metallurgical advantages (clean steel), CaO refractories have not yet found appreciable use because of hydration [78], [79].

Basic Bricks Containing Chrome. Most bricks of this type are fired mixtures of magnesia and varying amounts of chrome ore, usually in coarse to medium grain sizes. The refractory chrome ores consist of a chromite, a spinel $(Mg, Fe^{II})O \cdot (Cr, Al, Fe^{III})_2O_3$ of variable composition depending on the ore deposit, and greater or lesser amounts of a magnesium silicate. The extent of the silicate phase should be as low as possible. High-quality magnesia chrome bricks have a SiO_2 content of $< 2.5\,\%$ and a $CaO + SiO_2$ content of $< 3.5\,\%$. In contrast to magnesia bricks, the CaO/SiO_2 ratio and the B_2O_3 content have little influence on hot strength.

The following bricks are fabricated:

1) *Chemically bonded magnesia chrome bricks,* normally metal clad and with a chemical bonding agent (e.g., $MgSO_4 \cdot 7\,H_2O$); this type of product has become less important due to decreasing steel production in open-hearth furnaces
2) *Normally fired bricks,* with a predominant silicate bond between magnesia and chrome ore
3) *High-fired bricks,* with low SiO_2 content and a predominant direct bond between magnesia, residual chrome ore, and so- called secondary spinels (direct-bonded bricks)
4) *Bricks containing prereacted sintered or fused magnesia chrome grain* (rebonded basic bricks); the grain in this case contains a large amount of directly bonded phases

In magnesia chrome bricks with a low SiO_2 content the direct bond and a dense texture develop during firing at temperatures above 1750 °C. The first porous silicate bond that forms between the magnesia and chrome ore grains is subsequently displaced, and a dense direct bond arises between periclase/periclase and periclase/chromite or secondary spinels. At high temperatures spinel is dissolved in the silicate phase, and it precipitates as secondary spinel on cooling [80]. The silicate phase is isolated in pockets; i.e., the bricks show high hot strength and corrosion resistance. An improved dense texture is achieved by adding chromium metal powder [81].

Advantages of adding chrome ore to magnesia mixtures are better thermal shock resistance, increased corrosion resistance to slags with a CaO/SiO_2 ratio < 1.5 (acidic slags) due to the chromite, lower thermal expansion, and lower thermal conductivity.

Chromite bricks consist mainly of chrome ore and a small amount of magnesia. They are quite inert and very resistant to acidic and basic slags.

The wear characteristics of chrome-containing bricks are similar to those of magnesia bricks. Silicate melt penetrates behind the hot phase and spalling occurs. Alternating oxidizing and reducing atmospheres aggravate the attack. Iron oxide infiltration can cause the bricks to swell (bursting). In alkali and calcium environments chromite may decompose to form water-soluble, toxic Cr(VI) compounds. Chrome-bearing refractories are therefore used today only after careful consideration.

Applications: ladles and vessels for vacuum treatment of steel and argon oxygen decarburization (AOD) converters; rotating cement furnaces and glass furnace regenerators (bricks with low Cr_2O_3 content); open hearth furnaces; limited applications for chromite bricks.

Spinel-Containing Bricks. The magnesium aluminum spinel $MgO \cdot Al_2O_3$ is used in the refractory industry [82].

Spinel, $MgO \cdot Al_2O_3$ (71.7 % Al_2O_3, 28.3 % MgO), is the only compound in the system $MgO - Al_2O_3$, and it has a melting point of 2135 °C. First formation of a melt occurs at 2020 °C, so spinel can be classed among the high-temperature materials. With rising temperature the stoichiometric spinel $MgO \cdot Al_2O_3$ can incorporate MgO and Al_2O_3 into its lattice, resulting in spinel compositions ranging from about 66 % Al_2O_3 to 90 % Al_2O_3. Cooling or tempering leads to variable precipitation of MgO or Al_2O_3.

Sintered spinel raw materials are available with 66 – 90 % Al_2O_3, and fused spinels [83].

Magnesia-spinel bricks consist mainly of excess low-iron and low-SiO_2 magnesia together with sintered spinel. This brick type was developed as a chrome-free alternative to the magnesia chrome brick in rotating cement furnaces [84]. In the first step of development fine alumina grain was added to magnesia. On firing in situ, spinel formation occurs.

Ceramic-bonded fused spinel bricks are useful in glass furnace regenerators as an alternative to magnesia bricks in oil-fired furnaces. The spinel shows high resistance to attack by alkali and SO_3 (alkali sulfate).

A special type of spinel brick is the *picrochromite brick*, containing fused chrome spinel ($MgO \cdot Cr_2O_3$) grain, which shows extraordinary resistance to blast furnace slags and acidic coal ashes [85].

Forsterite Bricks [86]. The principal component here is magnesium orthosilicate, forsterite ($2\,MgO \cdot SiO_2$). Olivine is the main raw material, containing < 8 % FeO. During manufacture, magnesia is added to transform the FeO on firing into magnesium ferrite ($MgO \cdot Fe_2O_3$). Chrome ore or spinel additives are used to alter the properties, especially to increase thermal shock resistance. Forsterite bricks display good resistance to iron-containing slags up to 1400 °C, as well as to alkali attack.

In addition to fired forsterite bricks, unfired chemically bonded *olivine bricks* are on the market.

Applications: regenerators for glass melting furnaces, safety linings in the iron and steel industry (restricted use).

Figure 13. Thermal expansion of ZrO_2 ceramics
a) Fully stabilized; b) Baddeleyite; c) Ceramic-bonded AZS brick; d) Fusion-cast AZS brick; e) Partially stabilized

7.1.4. Zircon- and Zirconia-Containing Bricks [87] (Table 11)

The primary raw material for ZrO_2-containing refractories is zirconium silicate, $ZrSiO_4$ (mineral name: zircon), with a theoretical composition of 67.2 % ZrO_2 and 32.8 % SiO_2. It is stable to ca. 1800 °C, but the temperature for thermal decomposition into ZrO_2 (baddeleyit) and SiO_2 may be far lower depending on the type and amount of accompanying components. Chemical processing of zircon results in powdered zirconium oxide, which is worked up to various types of refractory raw materials (sintered and fused material, stabilized or partially stabilized materials).

Pure ZrO_2 (e.g., the mineral baddeleyite) has a monoclinic lattice, which is transformed reversibly beginning at about 950 °C into a tetragonal modification. This is stable to ca. 2300 °C, at which point it is transformed again into a cubic modification. The monoclinic – tetragonal transformation is accompanied by a volume change of ca. 7 % together with considerable hysteresis (Fig. 13), resulting in stress and cracking in pure ZrO_2 ceramics. Consequently, such ceramics cannot be manufactured. Addition of suitable metal oxides (for refractory purposes, mainly CaO, MgO, and Y_2O_3 in solid solution with ZrO_2) permits the cubic modification to be stabilized down to room temperature. A fully stabilized ZrO_2 can be achieved by the addition of about 5 – 10 % stabilizer. Partially stabilized zirconia raw materials are now used in most cases (3 – 6 % stabilizer added). This leads to smaller volume changes on heating and provides the additional advantage of creating microcracks, which increases the thermal shock resistance of the brick.

The following types of ZrO_2-containing products can be distinguished:

1) Ceramic-bonded zirconium silicate bricks
2) Ceramic-bonded $Al_2O_3 - ZrO_2 - SiO_2$ (AZS) products, manufactured from mixtures of zircon and high-alumina raw material
3) Fusion-cast ZrO_2-containing bricks, such as fusion-cast AZS bricks (see Sec. 7.1.9)
4) Stabilized or partially stabilized sintered ZrO_2 products (zirconia ceramics)

Zirconium silicate bricks are manufactured from zircon sand or prefired zircon grain, with powdered zircon and clay or only very fine zircon powder as a bonding agent. They are fired at ca. 1400 – 1600 °C. Shaping is accomplished by pressing, isostatic pressing, and slip casting. Depending upon the application, shapes with open porosities from 1 – 24 % are produced. The fired bricks contain a considerable amount of undecomposed $ZrSiO_4$ [88–90].

Bricks made from zircon and fused silica are used as hot repair materials because of their high thermal-shock resistance.

Ceramic-Bonded AZS Bricks. The raw materials here are zircon, corundum, calcined Al_2O_3, and mullite (also prefired cyanite). Depending mainly on the firing temperature, two types of products can be distinguished by their mineralogical composition: bricks containing corundum, mullite, and zircon; and bricks containing corundum, mullite, and baddeleyite.

In contrast to fusion-cast AZS bricks (see Section 7.1.9), the ceramic-bonded AZS bricks contain a very small amount of glassy phase and offer far better thermal shock resistance. They also show good resistance to molten glass.

Zirconia Ceramics [91], [92]. These are fabricated primarily by fine- ceramic production methods in dense (and therefore thermal-shock-sensitive), small, special shapes. High thermal resistance (melting point, depending on stabilizer, 2500 – 2600 °C) and good corrosion resistance characterize ZrO_2 ceramics. The type of stabilization determines thermal-shock and corrosion resistance. Destabilization may occur in contact with slags.

Applications: zircon- containing refractories are used in glass-melting furnaces (superstructure, bottom, feeders) and in the steel industry as ladle bricks and nozzles. Zircon bricks are resistant to oil residues and especially to V_2O_5. ZrO_2 materials are used as nozzles and sliding nozzle plates for the extremely corrosive conditions associated with the teeming of steel. Other refractory applications of ZrO_2 ceramics are in the ceramic industry as high-temperature kiln linings and kiln furniture.

7.1.5. Carbon and Graphite Bricks
(Table 12)

Carbon is unmeltable and not wetted by melts of metals, slag, or salts under oxygen-free conditions, but it is soluble in pig iron melt. Carbon resists the attack of many acids. High thermal conductivity (especially of graphite) and low thermal expansion impart high thermal-shock resistance. Applications of these bricks are restricted because of susceptibility to attack by oxygen, steam, and CO_2 above 400 °C.

Raw materials with the required grain size (low ash cokes, anthracite, natural and artifical graphite) are mixed together with tar or pitch in heated mixers and, while the mix is still hot, compacted by ramming or vibration. The cold, hardened shapes are subsequently fired at temperatures $\leq$ 1400 °C under the exclusion of air. Pure graphite shapes are produced by a second heat treatment (resistance heating) at ca. 3000 °C.

Depending on the crystallinity of the carbon or graphite and mixtures of the various raw materials, products can be fabricated with widely varying properties (thermal conductivity and oxidation, erosion, and alkali resistance). Addition of, e.g., Al_2O_3 or SiC increases corrosion resistance [93].

Applications: as large carbon blocks in the bottom and bosh of a blast furnace (→ Iron); linings for electric reduction furnaces (electrolytic aluminum cells, FeSi production); acid-resistant linings for the chemical industry. Because graphite- containing bricks display high thermal conductivity they are used as a heat-abducting medium in conjunction with water cooling systems in furnaces.

7.1.6. Carbon and Graphite-Containing Refractories (Table 13)

Combinations of different refractory raw materials with carbon (originating from a pitch or resin bond and/or graphite, mainly natural graphite) play a dominant role in the metallurgy of ferrous and nonferrous metals, and above all in the casting of steel.

When manufacturing pitch-bonded, resin-bonded, or impregnated products, preheated refractory grain and binder (usually $< 10\,\%$) are hot mixed (temperatures up to 160 °C depending on the viscosity of the binder) and hot pressed. Liquid resins or solutions containing curing agents (hexamethylenetetramines) allow cold mixing. Complete wetting of the graphite must be achieved. Resin hardening occurs at 200 °C (thermosetting). Impregnation of bricks with pitch or resin is carried out under vacuum and at the appropriate temperature (with resin solutions: room temperature) [29].

Heating causes volatile matter to be released and the "carbon bond" develops. The carbon yield ($\leq 70\,\%$ of binder amount) depends on the type of binder and the coking conditions. The release of volatile organic compounds requires environmental precautions during the production and use of organic-bonded refractories.

Several types of carbon- and graphite- containing refractory ceramics are produced:

1) Fired graphite- containing refractories
   a) *Chamotte – clay – silicon carbide–graphite shapes*, used mainly as crucibles for the melting and casting of nonferrous metals. These contain added SiC and silicon metal to increase oxidation resistance and strength. To minimize oxidation during firing under reducing conditions (≤ 1350 °C) and during use, such shapes

are glazed, or a glaze-forming additive is introduced into the mix. Silicon carbide crucibles are manufactured with a pitch bond; i.e., a carbon bond is formed during firing [94], [95].

b) *Chamotte – graphite and high-alumina – graphite shapes* for steel casting such as stoppers and nozzles.

c) *Pitch- and resin-impregnated fired bricks* (high alumina, magnesia, and dolomite products).

2) Pitch- and resin-bonded refractories

a) *Unfired pitch- or resin-bonded or tempered high-alumina bricks* (after coking, ca. 5 % C).

b) *$Al_2O_3 - SiO_2 - SiC - C$ bricks:* combinations of high-alumina raw materials, SiC (5 –15 %), and graphite (5 – 15 %), developed first for the transport and treatment of pig iron [96].

c) *Pitch- or resin-bonded, unfired or tempered magnesia, magnesia – dolomite* and *dolomite bricks and shapes* [97] (after coking, $\leq$ 6 % C, at which point additional carbon black is added up to 10 %).

d) *Pitch- or resin-bonded or tempered oxide – graphite products* [98–100] from mixtures of mainly pure oxides (sintered and fused grain) together with $\leq$ ca. 30 % graphite, with or without the addition of so- called antioxidants (metal or nonoxide powders), usually < 6 %. These include:

Corundum carbon and *zirconia carbon products,* used mainly as nozzles and shrouds for the continuous casting of steel. Addition of fused silica or ZrO_2- containing aggregates to corundum graphite products increases thermal shock resistance. Special additives like BN reduce the clogging of nozzles.

Magnesia carbon bricks and shapes, used for lining steel converters, for the slag area in ladles and steel refining vessels, and in electrical arc furnaces [101], [102]; also as nozzles for continuous steel casting.

Especially the oxide – graphite products combine the nonwettability of graphite crystals by metal melts and slag (no infiltration into the bricks) with the high corrosion and erosion resistance of dense oxide grain. These products have low open porosity (< 6 %) in the delivered state, but porosity after coking increases to ca. 10 – 12 %. Shapes for the casting of steel normally display a higher porosity (see Table 13) as well as high thermal-shock resistance [100].

The addition of metal powders (e.g., aluminum, magnesium, silicon) or alloys and/or nonoxide compounds like SiC, B_4C, or ZrB_2 inhibits carbon oxidation. Complex reactions occur between the brick components and the atmosphere (CO_2, CO, N_2) during heating in service, leading to such new compounds as Al_4C, which is said to increase strength, and spinel, which increases corrosion resistance. Secondary carbon may also precipitate [103]. The effects of graphite content on essential properties of graphite- containing refractories are shown in Figure 14.

Figure 14. Effect of graphite content on the properties of graphite-containing refractories
a) Slag penetration resistance; b) Thermal shock resistance; c) Oxidation resistance and hot strength with antioxidants; d) Thermal expansion; e) Thermal conductivity; f) Oxidation resistance and hot strength without oxidants

Carbon reduces oxides at high temperatures with the formation of suboxides or metal vapors. Reduction of MgO begins at ca. 1500 °C with the formation of carbon monoxide and magnesium vapors, which may destroy brick texture. On the other hand, the metal vapors can be oxidized in parts of the bricks to form a corrosion-decreasing dense MgO zone.

During service, carbon- containing refractories normally show only a small oxidized working zone, where the effects of corrosion mechanisms known from comparable non- carbon-containing refractories are evident. Carbon still present behind this zone minimizes a deeper infiltration of slag or metal.

7.1.7. Silicon Carbide Bricks [104–107] (Table 14)

These can be divided into two classes according to their SiC content: SiC- containing refractories with ca. 40 – 70 % SiC, usually in combination with chamotte and a clay bond; and SiC products with 70 – 100 % SiC and different types of binding (and therefore different properties).

The bonding types encountered are:

1) *Silicate or oxide bond,* where the SiC grains normally are bonded with about 10 – 20 % bonding clay, alone or in combination with fine Al_2O_3, leading to a mullite bond; hot strength is determined largely by the composition of the resulting glass phase
2) *Silicon nitride and sialon* (*SiAlON*) *bond*, produced by firing under a nitrogen- containing atmosphere a green mixture composed of Si – SiC, which may also include Al_2O_3 or other alumina-bearing compounds
3) *Selfbond*, whereby a SiC bond is achieved by adding silicon and carbon and firing in an oxygen-free atmosphere
4) *Recrystallized SiC,* where the bond phase (SiC) forms during high-temperature sintering (at ca. 2000 °C) by vaporization and condensation reactions of fine SiC particles

A special type is the *SiSiC ceramic*, an SiC product with an infiltration of silicon metal. The exceptional properties of SiSiC ceramics include high thermal conductivity, low thermal expansion, very good resistance to thermal shock, high hot strength, and abrasion resistance.

SiC is sensitive to oxygen and such oxygen-containing gases as water vapor. In an oxidizing atmosphere SiC begins to decompose to SiO_2 and CO or CO_2 at ca. 900 °C. Above ca. 1200 °C the SiO_2 layer that forms on the SiC grains becomes glassy and retards further oxidation. During installation it is especially important to take into account the susceptibility of the product to excess air in the temperature range 900 – 1100 °C. Oxidation can be largely prevented by a dense protective coating (e.g., an Al_2O_3 surface layer).

SiC is also sensitive to alkali melts, basic slags, chlorine gas, and metal melts other than lead, zinc, and copper. Alkali resistance can be increased by using a nitride bond.

Applications: blast furnaces, kiln furniture in the ceramic industry (maximum service temperature, 1500 °C), municipal incinerators and special refuse incinerators, retorts for zinc distillation, aluminum industry (submerged burner tubes), tubes for ceramic regenerators.

7.1.8. Fine-Grained Oxide and Nonoxide Ceramics [13], [14]

These normally very pure and highly refractory materials have not yet found appreciable application in the classical markets for refractories (exceptions include ZrO_2, Section 7.1.4, and SiC, Section 7.1.7) because of high price, a restriction to small or thin shapes, and often low thermal-shock resistance. The production

of nonoxide shapes demands special fabrication methods not yet adapted to the refractory industry. Nonoxide refractories (carbides, nitrides, borides) are prone to oxidation at relatively low temperature.

One of the most promising areas of potential development for fine ceramics is their use as engineering or functional refractory materials and in very special applications in industries such as steel.

Uses for special fine ceramics include:

Chromium oxide – used in highly corroded areas of glass tank furnaces (fiber glass production). TiO_2 is added as a sintering aid [89].

Tin oxide – used as an electrode material for electric glass-melting furnaces [89].

Silicon nitride-based materials – skid rails in reheating furnaces for the steel industry, anchors for fixing ceramic-fiber linings, aluminum industry (not wetted by aluminum melt).

Boron nitride-based composites with Si_3N_4 and AlN, tested also in combination with ZrB_2 and TiB_2 or mullite – break rings for horizontal continuous steel castings, reinforcement of the slag zones of submerged nozzles in continuous steel casting [108], [109].

Most special ceramics are very dense, but porous materials based on Al_2O_3, ZrO_2, and SiC with defined pore-size distribution are increasingly being used for filtering steel and nonferrous-metal melts, as well as for high-temperature filtration of gases.

7.1.9. Fusion-Cast Bricks [110]

Most fusion-cast products belong to the system $Al_2O_3 - SiO_2 - ZrO_2(-Cr_2O_3)$. The finely ground raw materials (alumina, zircon, zirconia, chrome ore, chrome oxide, special additives) are usually melted in an electric arc furnace and cast into sand or graphite forms. The shapes produced range from small parts to blocks with lengths up to 1 m or more. During the more or less rapid cooling process (for larger blocks, 6–20 d) the characteristic texture of a fused-cast brick develops: a dense structure (practically free of open pores) with intercrystalline bonding of the mineral phases. The fusion cast $Al_2O_3 - ZrO_2 - SiO_2$ (AZS) bricks contain a high content of a glassy phase (ca. 20 mass %), but it has no bonding function, simply filling the gaps between crystals.

The dense structure imparts high strength and both corrosion and erosion resistance. Disadvantages are low thermal-shock resistance and structural inhomogenities caused by contraction and segregation during cooling.

The various types of fusion-cast bricks are described in Table 15. A special feature of AZS fused-cast bricks is draining out of the glassy phase during first heating, which may lead to bubble formation in contact with glass melts. A newly-developed fused-cast ZrO_2 brick contains a special glassy phase that acts as a buffer against the transformation of baddeleyite [111], [112].

Applications: primarily in glass tank furnaces (→ Glass, Chap. 5.7.), regenerators for glass furnaces, reheating furnaces in the steel industry (skid rails).

7.1.10. Refractory Ceramics with Low Thermal Expansion

As in the case of glassy SiO_2, ceramics with low thermal expansion display extraordinarily high thermal-shock resistance, and they are especially qualified for service conditions involving frequent changes in temperature (e.g., kiln furniture).

These ceramics are products based on cordierite ($2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$), lithium aluminum silicates (eucryptite, spodumene, petalite) [113], and aluminum titanate ($Al_2O_3 \cdot TiO_2$) [114].

Cordierite products have acquired considerable industrial significance. Chamotte or cordierite – chamotte (with or without the addition of corundum or mullite) is bonded with cordierite-forming mixtures of clay, kaolin, talc, or magnesia through firing at ca. 1150 – 1350 °C. The cordierite content of the fired product is ca. 40 – 80 %. The maximum application temperature of normal cordierite shapes is 1250 °C. Addition of mullite and corundum increases both hot strength and service temperature [115] (Table 16).

Applications: kiln furniture.

7.2. Unshaped Refractory Materials [6], [27], [116–118]

Unshaped refractory materials, also called monolithics, are mixtures consisting of an aggregate (grains) and one or more bonds, prepared ready for use either directly or after the addition of one or more suitable liquids (usually water). These mixtures are either dense or insulating.

The CEN Draft Proposal of September, 1992 defines such products according to

1) Intended application:
   Materials for monolithic constructions
   Materials for repairs
   Materials for jointing
2) Product type and placement:
   Castables
   Gunning materials
   Moldable materials (mainly ramming mixes, plastic and tap-hole mixes)
   Refractory cements and mortars
   Others (mainly dry mixes, injection mixes, and coatings, each corresponding to various types of placement)
   Prefabricated shapes made from unshaped materials (mainly castables and moldables)

Classification within the various categories is based on the temperature below which the material does not shrink more than a specified amount (linear shrinkage 2 – 3 %).

Other classification schemes correspond to those for shaped products (see Chap. 3 and Table 1). Additional subdivisions are introduced to reflect application characteristics specified by the principal consumer – the iron and steel industry – in the form of a so- called "code for unshaped products" [119]. This code defines monolithics according to a duodecimal system based on such factors as state as received, type of binder, processing technique, major raw material, composition, and classification temperature.

Four main types of unshaped products can be identified according to chemical composition:

1) Aluminosilicate refractories, including products consisting mainly of aggregates of alumina, silica, and/or silico-aluminates
2) Basic refractories, mainly aggregates of magnesia, dolomite, chromite, and spinel
3) Refractories containing carbon (i.e., graphite or carbon together with other nonwetting agents), including mixes for troughs of blast furnaces [120]
4) Special products containing oxide or nonoxide aggregates different from the above (e.g., silicon carbide, zircon, zirconia)

The raw materials (see Table 2) and compositions of monolithics correspond essentially to those of shaped products. Their properformulation presupposes a thorough knowledge of raw material properties, composition (with special emphasis on bonding and special additives; see Tables 3 and 4), conditioning, and processing. This is due to the fact that a shaped product can be tested prior to application with respect to its suitabilty (e.g., nondestructively), while monolithic materials are transformed into a "shaped" product only after installation in a furnace or heat-up of a lining. This means that production errors have consequences at the time the product is applied, when all costs for the product, including the cost of installation and commencing operation in the facility to be lined with a refractory material, have already been incurred.

The advantages of unshaped refractories (e.g., shorter production and delivery time, quick and mechanized installation, monolithic lining,

flexible construction, and application) and enormous technical advances have led to a considerable increase in the use of monolithics (see Chap. 10). This development became possible because of the introduction of new binder combinations and special additives that result in material properties equal or superior to those of shaped products, as well as improved workability and economical new installation methods.

Unshaped refractory materials used in industrial linings are obviously not prefired. This means that the following factors must be taken into account:

1) A temperature gradient is incurred, one consequence of which is a corresponding property gradient (i.e., a drop in strength across the lining)
2) The maximum temperature at the hot face depends directly on the working temperature of the apparatus
3) Equipment life may be numbered in hours or years.

Figure 15. Comparison of open porosities of various fired unshaped refractory materials (60 – 90 % Al_2O_3)

Materials for Monolithic Constructions. An overview is provided in Table 17.

Ramming mixes are noncoherent before use. These are made up of refractory aggregates, bond(s), and (if necessary) liquid(s).

Processing is accomplished by hand or, more frequently, with the help of some mechanical device (pneumatic rammer, slinger, etc.) or vibration. Hardening generally occurs under the influence of heat.

Dry ramming mixes are a speciality product, often vibrated behind steel forms after mixing with a low-melting fritting agent (e.g., boric acid) or a thermosetting resin (hardening at ca. 200 °C).

Plastic mixes are ready-for-use products with a moldable, plastic consistency. The principal bonding agent is plastic clay. These mixes are supplied in a soft or preformed state (extrusion-pressed blocks). They are placed by ramming, vibration, pressing, or "extrusion". Preformed blocks require no molds for formation into a wall, but due to their high water content they shrink to a greater extent. Pitch- or resin-bonded tap hole mixes constitute a special type of moldable material.

Moldable mixes have many different applications, but they are being replaced to some extent by the far more satisfactory modern castables.

Refractory castables are supplied dry, and used after the addition of water or some other liquid followed by mixing. They are placed by casting with or without vibration (self-flowing), or by rodding, pumping, injecting, and sometimes tamping. Bond formation and hardening occur at ambient temperature. Hydraulic-bonded castables are the most common type of monolithics.

Two main families of castables are the *dense* and the *insulating* castables, with a limit of 45 vol % porosity (after total dehydration). Insulating castables are described in detail in [121]. Various types of dense castables are listed in Table 18.

Figure 16. Hot modulus of rupture of low-cement castables, ramming mix, and dense brick (corundum-based materials) [127]
a) LCC; b) ULCC; c) Brick; d) Dry ramming mix

The introduction of low- cement (LCC) and ultra-low- cement (ULCC) castables in the late 1960s led to completely new unshaped materials. Due to a drastic decrease in cement content

Table 17. Types of unshaped refractory materials

Type	Subdivision	Water content upon application, %	Nature of bond
Moldable mixes	dry ramming mixes (fritting mixes)	0 – 1	ceramic
	moist friable ramming mixes	3 – 6	ceramic, chemical, organic
	plastic friable mixes	5 – 8	ceramic, chemical, organic
	preformed plastic mixes	6 – 10	ceramic, chemical, organic
Refractory castables	dense castables	5 – 12	hydraulic, chemical
	insulating castables	10 – 50	hydraulic, chemical
Gunning mixes	moist friable mixes		hydraulic, chemical, ceramic
	different types of castables	5 – 50	hydraulic, chemical, ceramic
	special hot gunning mixes		hydraulic, chemical, ceramic (special binders)

Table 18. Types of dense refractory castables

Type	Classification according to ASTM C 401-89	Mixing water (approx.)	Essential components, bonding (see Table 3)
Conventional castable (CC)	> 2.5 % CaO	9 – 12	main hydraulic bonding: $CA^a + 10\,H^b \rightarrow CAH_{10}{}^c$ (< 20 °C) $2\,CA + 11\,H \rightarrow C_2AH_8{}^d + AH_3{}^e$ (20 – 35 °C)
Low-moisture conventional castable [122]		7 – 9	addition of ultrafine powders (high strength and abrasion resistance)
Low- cement castable (LCC)	1 – 2.5 % CaO	4.5 – 7	deflocculated castables containing aluminous cement, a minimum of 2 % ultrafine particles (SiO_2, Al_2O_3; < 1 micron) and at least one deflocculating agent
Ultralow- cement castable (ULCC)	0.2 – 1 % CaO		thixotropic rheological behavior (vibrational casting)
Clay-bonded castable	see LCC and ULCC	7	contains clay (flocculated) and aluminous cement as a deflocculant
Self-flowing castable [123]		6	consistancy (rheopex rheological behavior), which allows flow and deaeration without vibration
No- cement castable	< 0.2 % CaO		bonding: phosphate, alkali silicate, pitch or resin, Si, Al sol
Mixerless castable [124]			delivered ready-mixed with water for casting (vibrating); contains 0.5 % sodium silicate, thermosetting at 130 – 200 °C by gelation

[a] $CA = CaO \cdot Al_2O_3$. [b] $H = H_2O$. [c] $CAH_{10} = CaO \cdot Al_2O_3 \cdot 10\,H_2O$. [d] $C_2AH_8 = 2\,CaO \cdot Al_2O_3 \cdot 8\,H_2O$. [e] $AH_3 = Al_2O_3 \cdot 3\,H_2O$ (gel)

together with the presence of ultrafine powders (SiO_2, reactive Al_2O_3) and dense packing these castables require little mixing water and display low porosity and high cold and hot strength (due to e.g., mullitization of the matrix).

The composition of the binding-agent mixture of modern low- cement castables is based on a patent from the year 1978 [125]. This patent is the first to mention reduction of the cement content to 1 %. The increase in packing density is achieved by targeted changes in the microstructure through the use of a liquefier and adjusted grain sizes in the super-fine range (< 10 µm).

Figures 15 and 16 describe properties of modern castables, classifying them within the broader context of unshaped materials and comparing them to shaped products.

Conventional fireclay and high-alumina castables develop an anorthitic/gehlenitic ceramic bond when heated above ca. 1100 °C. In conventional corundum castables a high-temperature-resistant calcium aluminate bond develops. The addition of fine SiO_2 powder leads to mullite in low- cement castables, increasing their hot strength.

Compared to conventional castables, modern castables offer better corrosion resistance (due to a lower CaO content), low porosity, and small pore size [126]. Drying and first heat-up steps require careful monitoring to prevent explosive effects caused by excessive vapor pressure inside the lining. For the rheological and setting behavior (hydration), drying, and heat-up of castables see [6], [26]. Prior to heating a castable must be cured for a sufficiently long time (i.e., 24 h) to ensure full hydration and strength. Workability and setting time can be adjusted by the presence of small amounts (e.g., 0.1 %) of special additives. Modern castables require exact dosages of additives and mixing water, thorough mixing, and appropriate forming to achieve high-quality linings or shapes.

Gunning materials are specially prepared for placement by pneumatic or mechanical projection means in cold and also hot application. These may be castables to which water has been added during or prior to gunning, or they may be plastics. Various special bonds have been developed for achieving a dense and adhesive gunned layer. Such materials are used mainly for repairs, especially in the iron and steel industry.

Prefabricated shapes [128] are rammed or cast, and may be pretreated by the manufacturer as a way of providing blocks that are ready for use. Relatively large-volume parts are fabricated and preheated up to 600 °C at the refractory plant. The advantages of prefabricated shapes are:

1) *Optimal Manufacture*. Production of the prefabricated shapes benefits from the special know-how of refractory producers, enabling them to avoid faults during manufacture.
2) *Simple Lining*. Faults in the resulting lining are avoided as a consequence of simplified assembly.
3) *Short Installation Times*. This reduces the cost of refractory lining, although special mechanical equipment is required for handling.
4) *No Drying*. Prefabricated shapes have already been tempered, so on-site drying of the refractory material is not necessary (except for a brief preheating), which reduces energy costs considerably.

Jointing and coating materials are essential for establishing a safe refractory brickwork or lining surface. Such products are fine-grain materials whose characteristics and composition must correspond to those of the associated bricks. Table 19 describes such materials.

Table 19. Joints and coatings [3]

Material	Mixing liquid or water, %	Type of bonding
Refractory mortars	10 – 25	chemical, hydraulic, ceramic
Refractory mastics	12 – 30	chemical
Adhesives	30 – 80	chemical
Trowelling materials	15 – 30	chemical, hydraulic, ceramic
Coatings	30 – 60	chemical

Laying and jointing materials can be classified as follows:

1) *Refractory mortars,* with ceramic bonding starting at 800 °C and chemical or hydraulic bonding starting at 20 °C
2) *Refractory mastics,* with chemical bonding (i.e., high strength) above 110 °C
3) *Adhesives,* with chemical bonding as for refractory mastics, but finer grain size

The lining procedure has been mechanized, and is in most cases very efficient. Various lining methods have been developed. The properties and service behavior of a monolithic lining depend to a great extent on careful and appropriate preparation of the mix, as well as proper lining procedure, curing, drying, and first heat-up.

Applications: principal applications of materials for monolithic construction are in the iron and steel industry, foundries, the petrochemical industry (especially insulating gunning mixes), and incinerators.

7.3. Heat-Insulating Ceramic Materials [129]

Ceramic materials with a high pore volume (i.e., low thermal conductivity) are used extensively for thermal insulation of furnaces and auxiliary equipment. Apart from the effect of decreased thermal wall losses, the low weight of the insulating ceramic material allows lighter furnace construction and low heat-storage losses in discontinuous service.

Thermal conductivity depends not only on total porosity (overall gas volume) but also to a considerable extent on pore size and pore distribution, as well as texture ("thermal bridges") and mineralogical composition. Normally, the finer the pores, the lower the thermal conductivity. A maximum pore size of < 1 mm is the target. Microporous materials have a thermal conductivity lower than air. Above 1000 °C thermal radiation must be taken into account as a heat-transfer mechanism.

The optimal range for porosity or bulk density of a thermal insulating material can be chosen on the basis of the effective conditions for heat transport as a function of temperature [130].

High porosity implies low mechanical strength, high gas permeability, and low corrosion resistance, all of which must be considered in the use of insulating refractory materials. Furthermore, a porous texture leads to lower volume stability at high temperatures than in the case of dense materials (greater sensitivity to over-heating) and a greater susceptibility to reducing atmospheres (reduction of, e.g., Fe_2O_3; increased shrinkage) [131].

The main groups of insulating ceramic products are:

1) Insulating bricks
2) Insulating refractory bricks
3) Ceramic fibers
4) Porous or dense grains and granules of ceramic materials used as poured back-up insulation
5) Insulating castables (see Section 7.2)
6) Special insulating products based on calcium silicate and microporous high-SiO_2 materials,with application temperatures ≤ 1100 °C

Insulating ceramic materials are used mainly for rear lining behind a dense wear lining. Bricks and ceramic fiber products can be placed in direct contact with heat or a flame provided the furnace walls are not under high mechanical stress, there is no corrosion, and application limits are not exceeded.

7.3.1. Insulating Bricks

Insulating bricks are based on diatomite (moler), vermiculite, and perlite, with bulk densities of ca. 0.45 – 0.8 g/cm^3, cold crushing strength of ca. 1 – 7 N/mm^2, and a thermal conductivity at 200 °C of 0.1 – 0.2 W m^{-1} K^{-1}. They are normally used up to 800 °C, but low-flux diatomite bricks may be applicable to 1100 °C. Diatomite bricks have very fine pores, low thermal conductivity, and relatively high strength and abrasion resistance.

7.3.2. Insulating Refractory Bricks

According to official definitions, insulating refractory bricks have a total porosity of at least 45 % and an application temperature of at least 800 °C. Porosity normally lies between 60 and 80 %.

The criteria for classification (ISO 2245) are as follows:

1) The temperature at which the material does not show a permanent linear shrinkage greater than 2 %
2) The bulk density (which for a given product is directly related to porosity, and consequently to thermal conductivity)

Classification temperatures are not to be taken as acceptable service temperature limits, which depend on the particular service conditions.

Insulating refractory bricks are usually fabricated from fireclay (chamotte), sillimanite or mullite, corundum, and silica as raw materials, together with a combustible material. Special types include anorthitic-bonded fireclay bricks (ca. 15 % CaO) and bricks made from bubble alumina.

Types and properties of insulating refractory bricks are summarized in Table 20.

7.3.3. Refractory Ceramic Fibers [132–134]

(→ Fibers, 5. Synthetic Inorganic)

A proposed definition describes ceramic fibers as synthetic mineral fibers suitable for use as heat-insulating materials and containing less than 2 wt % alkali metal or alkaline earth oxides. Most ceramic fibers are based on glassy or crystalline aluminosilicates and crystalline corundum.

Table 20. Properties of insulating refractory bricks

Type	Classification temperature, °C	Al_2O_3, %	SiO_2, %	Fe_2O_3, %	Bulk density, g/cm^3	Porosity, %	CCS ∗, N/mm^2	Thermal expansion, 1000 °C, %	Thermal condutivity, 1000 °C, W m^{-1} K^{-1}
Silica	1500 – 1600	1	92 (3.5 % CaO)	< 0.5	0.8 – 1.2	50 – 65	3 – 4	1.2	0.5 – 0.8
Anorthite fireclay	1100 – 1250	36	45 (15 % CaO)	0.7	0.5	85	1	0.6	0.2
Fireclay	1250 – 1400	35 – 42		< 1.7	0.55 – 1.3	55 – 75	2 – 8	0.5 – 0.6	0.3 – 0.5
High-alumina 50 – 75 % Al_2O_3	1400 – 1700	55 – 75		< 1.5	0.8 – 1.5	45 – 75	2 – 12	0.6 – 0.7	0.35 – 0.55

Forsterite	1500	MgO 57	34	6	1.7	45	2.5	1.2	0.8

∗ Cold compressive strength.

Glassy (*amorphous*) *refractory ceramic fibers* (Al_2O_3 content ca. 45 – 60 %) are produced by fusing an aluminosilicate raw material (e.g., calcined kaolin) and/or sand and calcined alumina. Addition of ZrO_2, Cr_2O_3, B_2O_3, and other materials leads to changes in the properties of the fiber. The molten stream is attenuated into fiber form either by impact with a high-velocity jet of air and/or steam or by downward flow onto rotating wheels.

Polycrystalline fibers (62 – 100 % Al_2O_3) are sol – gel derived fibers from, e.g., aluminum salts, colloidal silica, organosilane, and modifiers. Rotary spinning (short staple fibres) is also practiced, as is the production of continuous filaments. After formation the fiber must be dried and calcined. Other types of oxide fibers (e.g., ZrO_2 fiber) are produced in the same way. This type of fiber is relatively expensive. To improve cost-effectiveness, polycrystalline fibers are often blended with low- cost glassy fiber. Properties and application temperatures for fibers and fiber products are shown in Table 21.

The fiber is used in loose form or processed into any of a variety of flexible or essentially rigid forms. Blankets and textiles (ropes, yarns) are examples of products made by an air-laid system. Papers, felts, and boards are produced by wet-laid systems (like the traditional paper-forming process). Boards and special shapes are processed via vacuum casting. The ceramic fiber is slurried in water with organic and/or inorganic binders (e.g., SiO_2 sol) and fillers. The slurry is dewatered onto molds via a vacuum. Fiber is also used in unshaped refractory materials like gunning mixes and castables. Products include ceramic-fiber veneering elements, folded modules, and ready-for-use system blocks with anchoring.

Ceramic-fiber products have very low bulk density (0.05 – 0.3 g/cm^3; i.e., a porosity > 90 %) and unusually low thermal conductivity. In contrast to insulating bricks, thermal conductivity of ceramic-fiber products decreases with increasing bulk density. Thermal conductivity increases more with increasing temperature than in the case of comparable insulating bricks (Fig. 17). Thermal shock resistance is extraordinarily high.

Figure 17. Thermal conductivities of insulating bricks a) Fireclay insulating brick; b) Microporous material

Table 21. Ceramic fibers and fiber products[a]

Type of fiber	Al_2O_3, %	SiO_2, %	Cr_2O_3, %	ZrO_2, %	Liquidus temp., °C	Classification temp., °C	Fiber diameter, µm	Density, g/cm^3	Maximum service temperature (°C)		
									Oxidizing atmos., continuous	Oxidizing atmos., discontinuous	Reducing atmos.
Glassy, amorphous	47	52			1760	1250	2–5	2.58	1100	1250	< 1100
	63	36			1800	1400	3–6	2.63	1200–1400	1400 (1500[b])	ca. 200° lower than in oxidizing atmos.
	41	55	3		1785	1400	2–5	2.61	1200–1400	1400 (1500[b])	ca. 200° lower than in oxidizing atmos.
	35	50		15	1810	1450	≈3	2.60	1200–1400	1400 (1500[b])	ca. 200° lower than in oxidizing atmos.
Polycrystalline	85	15			1950	1600	≈7	3.40	1500	1600 (1700)	ca. 100° lower than in oxidizing atmos.
	95	5			2000	1600	≈3	3.58	1500	1600 (1700)	ca. 100° lower than in oxidizing atmos.

[a] For fiber products in general, the bulk density is 0.05–0.3 g/cm^3 (special products, ≤ 1.3 g/cm^3). Thermal conductivity ranges are 0.08–0.12 W m^{-1} K^{-1} (400 °C) and 0.16–0.40 W m^{-1} K^{-1} (1000 °C). Fiber tensile strength 400–1500 N/mm^2. [b] Mixed fiber from high-alumina glassy fiber and alumina fiber.

Ceramic-fiber products are classified into groups according to the temperature (in 50 °C steps) at which the material does not show more than 4 % shrinkage.

Long-time application of ceramic fibers at maximum service temperature is limited significantly by shrinkage, crystallization and/or recrystallization (crystal growth). Up to 75 % mullite (beginning at 950 °C) and up to 40 % cristobalite (beginning at 1200 °C) can crystallize from amorphous fibers. At high temperatures the fiber becomes brittle, fragile, and subject to crumbling. Compressibility and elasticity are also lost. A crystalline alumina fiber shows crystal transformations (γ-Al_2O_3 to α-Al_2O_3) and crystal growth. Normally, alumina fibers contain about 5 % SiO_2, which is introduced to slow crystal growth; mullite (ca. 20 %) is also formed. In mixed products from glassy and alumina fibers the formation of mullite in service decreases shrinkage [135]. Mullite fibers are more volume-stable at high temperatures [136]. Impurities acquired from a furnace atmosphere (e.g., alkalies) may greatly increase shrinkage and crystal transformation. Ceramic-fiber products are sensitive to mechanical stress as well (e.g., to high-velocity gas streams). Improvement is achieved by brush-like orientation of the fibers perpendicular to abrasion stresses, or by impregnating the surface with SiO_2 sol or the use of rigid ceramically-bonded and prefired shapes.

Applications. Ceramic fibers have found application in all types of low- and high-temperature thermal processes, from use as a filler for joints or seals and insulation over veneering of furnaces walls up to complete fiber-lined furnaces (e.g., in the ceramics industry, and heating furnaces for the steel and glass industries). Most ceramic-fiber products have a service limit in long-time applications of ca. 1500 °C, although in special cases they may be used discontinuously up to 1750 °C.

In the nonferrous industry preshaped parts made from ceramic fibers have found application in direct contact with molten aluminum and copper alloys.

Proper construction and the use of appropriate joining techniques (glueing procedures, anchoring systems) are important factors in the lifetime of fiber furnace linings.

8. Selection, Use, and Industry-Specific Consumption of Refractory Ceramics

The service performance of a refractory material depends in roughly equal measure on:

1) The properties of the refractory material
2) The construction, lining and brick design, installation technique, drying, and initial heating
3) Service conditions

Most data sheets accompanying refractory products specify a service temperature limit or maximum service temperature. This refers to the maximum temperature to which the refractory can be exposed during operation without corrosive influences (heating on one side only). No test yet exists for determining the maximum service temperature. Consequently, the indicated temperatures are based on practical experience supported by suitable hot tests (refractoriness under load, hot strength, reheat change). Classification temperatures for refractory products are not to be considered as service temperature limits, which are usually lower.

In most cases, refractory ceramics are subject to a multitude of thermal, thermomechanical, mechanical, and corrosive stresses. Corrosion is the factor most likely to change the service properties of a refractory material in a significant way. A refractory material must be selected in accordance with those properties that are most important for a given service application. This requires close consultation between the refractory producer, the furnace builder, and the user. Often a refractory ceramic is "tailor made" for a specific application.

The output (tonnage) of refractory products is distributed among various industries in approximately the following way:

Iron and steel industry	55 – 60 %
Cement and lime industry	5 – 8 %
Glass industry	5 – 8 %
Ceramic industry	5 – 8 %
Nonferrous industry	2 – 5 %
Chemical and petrochemical industry	2 – 4 %
Energy-producing industry	2 – 4 %

A high proportion of unshaped refractories (ca. 80 %) is directed toward the iron and steel industry and foundries. Other consumer industries, with the exception of the petrochemical industry, use mainly shaped refractories. Jointing materials, which are included among the unshaped refractories, account for ca. 3 – 5 % of total refractory production. Table 22 provides information on consumption of refractory materials by the iron and steel industry.

The glass industry consumes ca. 0.5 – 1 kg of silica bricks, 1 – 3 kg of basic bricks, and 1 – 3 kg of fusion- cast bricks per tonne of manufactured glass. Consumption in the cement industry is ca. 0.4 – 1.2 kg of refractory per tonne of cement clinker.

Ceramic fibers are used to the extent of ca. 40 % in the process industry (industrial furnaces, kiln construction, and thermal processing) and ca. 25 % in the iron and steel industry [137].

Basic information regarding refractory applications in industrial furnaces, kilns, and ovens, including typical service conditions, is provided in [1]. For a short general overview of the application of refractories in various industries see [138], [139]; for details regarding construction and lining see [14] and [6].

The following list summarizes comprehensive references to the use of refractory ceramics in several industries:

Iron and steel industry	[8], [140–145]
Foundries	[7]
Nonferrous metal industry	[146]
Coke ovens	[62–64]
Cement and lime industry	[147], [148]
Glass industry	[9], [61], [110], [149]
Ceramic industry	[150]
Chemical and petrochemical industry	[151–153]
Energy-producing industry, incinerators	[151], [154], [155]

9. Toxicology and Occupational Health

Industrial hygiene and environmental pollution considerations in the refractory industry are increasingly the subject of national and international regulations and laws. Maximum concentrations have been established for emissions during the fabrication of refractories (gases such as fluorine, chlorine, and sulfur compounds in flue-gas, dust particles) [156] [157] and for concentrations of hazardous substances in the air at

Table 22. Consumption of refractories by the iron and steel industry, expressed in kilograms of refractory material per tonne of crude steel

Country	Bricks		Unshaped refractories	
	1985	1991	1985	1991
Federal Republic of Germany	10.7	8.0	6.4	5.8
Japan	7.3	5.5	6.3	6.1

Figure 18. Evaluation of the production of different types of refractories

the workplace [158], [159]. Irritating, harmful, and toxic substances in raw materials (especially binders) and refractory products are indicated in product safety data sheets and marked on packages.

The main groups of hazardous or potentially hazardous substances are: chromium compounds (hexavalent chromium and soluble materials) [160]; SiO_2, i.e., amorphous and all crystalline forms of silica; organic binders (especially pitch) [29], [161]; fibers [162]; boron oxide; and oxides of heavy metals (traces).

10. Economic Aspects [163–166]

The refractories industry represents an independent branch of the ceramic industry. According to [1], about 800 manufacturers worldwide produce refractory ceramics. About 300 manufacturers in the EC produce refractory ceramics. Competition exists between large, increasingly international corporations, medium-sized and small companies, with the latter especially active in the production of unshaped refractory materials. Refractory production data from several regions are presented in Table 23.

The estimated value of refractory production in the EC during 1986 was € 2.8×10^9, ca. 36 % of which could be attributed to the Federal Republic of Germany.

There has been a steady decline in refractory production in all industrialized countries since about 1960, which can be ascribed to a reduction in specific consumption in most user industries together with technological advances resulting

Table 23. Production data for refractory materials

Source	Output, 10^6 t					
	Bricks		Unshaped refractories		Total	
	1988	1991	1988	1991	1988	1991
EC	3.1	2.8	1.8	1.6	4.9	4.4
USA	1.2		0.9		2.1	
Japan	0.95	0.9	0.8	0.8	1.75	1.7
USSR					ca. 10	

in higher quality refractories with a longer life span. Further reduction of overcapacity is necessary.

A shift from mass production of generalized refractories to high-quality and specialized products with diverse properties and applications, and to high-priced "high tech" refractories [167], is quite apparent. Figure 18 provides relative evaluations of different types of refractories used in Japan, which serves as an example of a highly industrialized country. The steady increase in the proportion of unshaped refractories is worth noting.

The following list offers relative price comparisons for several types of refractory supplied as standard-sized bricks:

Fireclay (conventional)	1
Fireclay castable (conventional)	1
High-quality fireclay brick	1.5
Bauxite brick	2
Corundum brick (85 % Al_2O_3)	5
Magnesia brick (conventional)	2.5
High-quality magnesia brick	4.5
Magnesia graphite brick	5
Dolomite brick	0.9
Zircon silicate brick	4
SiC brick (95 % SiC)	7
Fusion- cast brick	10

Refractory Ceramic Fibers. According to [137], total global capacity for ceramic-fiber production increased in 1990 to ca. 190 000 t/a (1.9×10^6 m^3/a) for fibers containing 45 – 60 % Al_2O_3 and about 1500 t/a (15 000 m^3/a) for fibers with 72 – 97 % Al_2O_3. Average selling prices range from ca. € 26/kg for loose glassy fibers to € 307/kg for high-temperature boards and shapes.

Further developments in refractory materials are subject to the following influential factors [163], [165], [168–170]: consumer demand, availability, properties and price of raw materials, automation, and environmental restrictions.

1. Introduction, Classification

Reinforced plastics, also called polymer composites, are now an important class of engineering materials. They are distinguished by attractive mechanical properties and corrosion resistance, unique flexibility in design capabilities, and ease of fabrication. The word "composite" means "consisting of two or more distinct parts." Polymer composites consist of one or more discontinuous phases embedded in a continuous-phase polymer matrix.

The discontinuous phase is usually harder and stronger than the continuous phase, and is called the reinforcement. The matrix can be classified as thermoplastic (capable of being separately hardened and softened by increases and decreases, respectively, in temperature) or thermoset (changing into a substantially infusible and insoluble material when cured by the application of heat, or through chemical means).

The properties of composites are strongly influenced by the properties of their constituents and the distribution and interactions among them. The constituents usually interact in a synergistic way, providing properties that are not accounted for by a simple volume-fraction sum of the components. Along with the volume fraction and the distribution of discrete units in the discontinuous phase, the interfacial area plays an important role in determining the extent of interaction between the reinforcement and the matrix and – in this way – the final properties of the composite. The fabrication technology of composites, as well as some of their physical properties, is dominated by the chemistry and rheology of the matrix resin and by the type and physical form of the reinforcement.

The use of reinforcing agents makes it possible for any thermoset – or thermoplastic – matrix property to be improved or changed to meet varying requirements. Most polymer composites developed thus far have been fabricated to improve mechanical properties such as strength, stiffness, or toughness. The strengthening efficiency of the discontinuous phase plays the most important role in these products, and the strengthening mechanism depends strongly on the geometry of the reinforcements. Therefore,

polymer composites can be classified according to reinforcement geometry [9]. The three major classes of polymer composites are fibrous, laminar, and particulate. The commonly accepted classification scheme for polymer composites is presented in Figure 1.

1.1. Fiber-Reinforced Polymers

Fibrous composites consist of reinforcing fibers embedded in a matrix. All fibers are characterized by a high aspect (length-to-diameter) ratio. This results in a high surface – volume ratio, permitting good anchorage of fibers within a matrix. Fiber reinforcement can be either continuous or discontinuous. Fibers are generally much stronger and stiffer than the surrounding polymer matrix, but they are small in diameter, and bend easily when pushed axially. Although such composites may have outstanding tensile strength, support is essential to prevent individual fibers from bending and buckling. Thus, the principal purpose of the matrix is to function not as a load-bearing constituent but essentially to bind the fibers together and protect them. Fiber-strengthening efficiency is highest when the direction of loading corresponds to the orientation of the fibers. In the transverse direction, properties of the matrix and the quality of the fiber – matrix interface predominate. The combination of matrix and fibrous elements results in a composite structure that may assume different structural forms depending on the forming and processing methods used.

Because the fibers are oriented in a particular direction, material properties may vary with direction. Such a material is referred to as "anisotropic." Many types of anisotropic materials exist, with special designations such as orthotropic, transversely isotropic, and cubic. The fundamental building block for fiber-reinforced plastics is an element with a unidirectional (UD) but transversely random array of fibers embedded in a surrounding matrix, as illustrated in Figure 2. Thus, a unidirectional composite is transversely isotropic (axes O_T and O_P can be selected arbitrarily). In the $O_L - O_T$ plane, however, the properties of a UD lamina are strongly dependent on direction (Fig. 3). The longitudinal properties of UD composites are controlled by the fiber, whereas transverse properties are matrix-dominated. The transverse properties are unsatisfactory in most engineering applications, a problem which is overcome by bonding together two or more laminae to act as an integral

structural element displaying the desired properties in all directions. Combining layers with different properties or different orientations gives the designer the ability to tailor a laminate (provide the optimal configuration) for a particular set of loading conditions. However, in applications where the stress may not be predictable, or where stresses are likely to be approximately equal in all directions, the composites themselves must have approximately equal strength in all directions.

Figure 2. Basic element of fiber-reinforced plastics; coordinate system
O_L = longitudinal; O_T = transverse; O_P = perpendicular

Figure 3. The directional nature of UD lamina properties (E, G, α – Young's modulus, shear modulus, and coefficient of thermal expansion)

An effective way of producing such an isotropic composite material is to use randomly oriented short fibers as reinforcement. Molding compounds consisting of short fibers are usually capable of producing isotropic composites. In short-fiber composites, the so called fiber-end effect plays an important role, and composite properties become a function of fiber length. Loads are not applied directly to the fibers in a composite, but are transferred instead by the matrix to the fiber surface through nonuniform shear stress acting along the fiber – matrix interface (Fig. 4). The tensile stress in the fiber reaches a maximum at the fiber midpoint. The *critical length* of a fiber can be defined as the minimum length at which the ultimate strength of that fiber is reached. Interfacial strength is influenced strongly by the effectiveness of bonding between the fiber and the matrix via coupling agents. The higher the interfacial strength, the shorter is the length that will ensure full exploitation of the fiber's strength.

In the case of short-fiber injection-molded composites, some fibers will have aspect ratios lower than the critical value. These fibers cannot contribute effectively to overall composite strength. Compounding and molding cause fibers to undergo attrition, resulting in a broad distribution in length and a significant fraction of fibers falling below the critical length. In long-fiber injection-molded composites, the mean fiber length is typically 10 times as great as in short-fiber composites. Thus, a higher proportion of the fibers remains effective in load-bearing situations, and the composites themselves are stronger than their short-fiber counterparts. Figure 4 shows that a small region adjoining the fiber end is subject to less than the maximum fiber stress. This in turn affects the elastic modulus. When the fiber length is much greater than the critical length, composite behavior approaches that of a continous-fiber-reinforced polymer. The tensile strength of a composite is more strongly dependent on interfacial bond strength than is its tensile modulus. This is evident in particulate fillers, where the aspect ratio approaches 1. Here the addition of filler contributes to an increase in modulus but generally to a decrease in the strength of the composite.

In general, the incorporation of reinforcing fibers into a polymeric matrix increases short-term stiffness and strength, increases creep resistance and fatigue endurance, and reduces the influence of temperature on all of these properties. Thermal expansion can be reduced as a way of improving dimensional stability.

Impact strength, which is related to the toughness of a material, is reduced in some polymer composites, a circumstance that can be influenced by several factors. The loading of

Figure 4. Distribution of tensile stress σ and shear stress τ in short fibers aligned with the load (l = length, l_c = critical fiber length)

fibers may transform the failure mode from ductile to brittle, which can in turn lower impact strength. However, this reduction can be counteracted, at least to some extent, if interfacial adhesion between the polymer matrix and the reinforcement permits the absorption of impact energy through debonding. Nevertheless, in systems where matrix-governed ductile failure occurs, increased interfacial adhesion generally improves impact strength.

1.2. Particulate Polymer Composites

By definition, a particle is nonfibrous; it generally lacks a long dimension, and is not effective in improving fracture resistance when added to a polymer matrix (with the exception of rubberlike particles in brittle polymer matrices, which contribute to an improvement in fracture resistance by promoting and then arresting crazing). Despite this definition, polymers containing very short fibers are generally classified as particulate composites. The introduction of hard particles into a polymer matrix leads to a reduction in strength due to stress concentration in the adjacent matrix material.

The two basic reasons for adding particulate filler or reinforcement to a polymer are (1) to fill the system (i.e., replace some of the more expensive polymer with less expensive filler) and (2) to modify properties of the matrix material (e.g., thermal or electrical conductivity), improve processibility, reduce friction or shrinkage, improve performance at elevated temperature, increase wear or abrasion resistance, improve fire retardancy, provide color, and improve appearance.

Platelet-shaped particles, such as flakes, can also serve as reinforcing agents. They offer two-dimensional geometry and, when placed parallel to each other, can be packed more closely than fibers or spherical particles. However, such possibilities have not been fully exploited due to fabrication difficulties. In terms of reinforcement, the longer the particles, the better is the reinforcement. Most particle-filled polymers are manufactured by injection molding, however, so a balance must be struck in terms of a particle length that gives both optimum properties and good processibility. If relatively long fiberlike particles are used as filling, their distribution and orientation may change within the molding. The flow of fiber-filled plastics into a mold during injection molding is a very complex process, and ensuring flow-induced orientation in the optimum direction is difficult. On the other hand, sometimes the challenge is to minimize undesirable effects of anisotropy (e.g., warping and postmolding shrinkage), which may be accentuated by the flow-orientation of fibers. In these cases particulate fillers may be preferable to fibers.

1.3. Laminar Polymer Composites

Laminar composites consist of at least two different layers (laminae) bonded together into one composite piece. Such layers may differ in material, form, or orientation. Combinations of matrix, fibrous mat, aligned fibers, cloth, paper, and other materials can be laminated together in either continuous or discontinuous processing.

Because of the nearly unlimited variety of possible combinations of layers, material forms, and orientations, generalization regarding laminar design is difficult. This great variety offers the designer considerable freedom in both laminate composition and product form. The unique properties obtained with layered construction encourage the designer to develop composite materials that meet new and innovative design parameters.

The principal design criterion is appropriate fiber orientation within each layer. Polymeric composite structures that incorporate continuously oriented fibers laid in plies can be radically anisotropic in nature. Strength, stiffness, and coefficients of thermal or moisture expansion can all vary more then tenfold in different directions (cf. Fig. 5). Whereas the in-plane strength of such materials may be comparable to the strength of metals, for example, strength in the through-thickness direction can be lower than that of pure matrix. Differing properties of the different layers (e.g., thermal expansion, stiffness) may lead to considerable residual stress when a polymer matrix is cured at elevated temperature. Interlaminar stresses induced through external loading may also be significant, and can cause distortion when the layer-stacking sequence is not symmetric and situated symmetrically to the midplane (Fig. 6).

The theory of laminates has been elaborated [9–17], and many computer programs are now available to help determine the optimal configuration of a laminate under specific conditions; [e.g., LAMINATE (Engineering Software, Dallas, Texas), COMPCAL and CYCLAN (American Society for Composites, Dayton, Ohio), MIC-MAC (Think Composites, Dayton, Ohio), and CADFIBER (IKV, Aachen, Germany)]. In addition to these general programs, many special software packages are being developed for special tasks (e.g., computation of fatigue and crack propagation).

Figure 6. Distortion of an unsymmetrical laminate due to (a) load and (b) temperature change

2. Reinforced Plastic Components

2.1. Reinforcing Fibers (→ Fibers, 4. Synthetic Organic; Fibers, 5. Synthetic Inorganic)

As a rule, fibers used for reinforcement purposes are rather fine, ranging from 2 to 20 μm in diameter. The main exception is boron fiber, available in diameters up to 200 μm. Fibers are typically stronger and stiffer than a corresponding bulk material. Fiber strength generally decreases with increasing diameter and length (Fig. 7). A high fiber aspect ratio permits an effective transfer of load to the fibers via the matrix, which makes such fibers an excellent reinforcing agent.

The major categories of synthetic reinforcing fibers are glass, graphite (carbon), boron, organic, metallic, and ceramic. Natural fibers (asbestos, jute, and sisal), formerly used for economic reasons, have now been generally supplanted by synthetics (in the case of asbestos, because of adverse health effects).

Synthetic fibers are usually prepared in continuous processes and then converted into a form suitable for their intended composite application. The major finished forms are continuous roving, woven roving, fiber mat, chopped strand, and yarn for textile applications.

Figure 7. Dependence of fiber strength on gage length
a) Mean filament strength; b) Strength of fiber roving; c) Strength of fiber roving saturated with polyester resin

The form of reinforcement varies with the fabrication process. Three categories can be distinguished: In the first, fibers are placed directly on the component being manufactured. Examples are the filament winding (Section 3.3) and spray-up contact (Section 3.2) molding processes. The second group includes those processes in which a sheet, web, or preform of fibers is prepared and placed in position on a mold where it comes in contact with a resin (e.g., resin-transfer molding, Section 3.11). The third category consists of processes involving the preparation of a compound of fiber and plastic that can flow during molding. Sheet molding compounds (Section 3.6), bulk molding compounds (Section 3.8), and short-fiber-reinforced thermosets and thermoplastics are typical examples within this category.

2.1.1. Glass Fibers (→ Composite Materials; Fibers, 5. Synthetic Inorganic, Chap. 2.)

Glass fibers constitute the most widely used form of synthetic composite reinforcement. Chemically, glass is an amorphous material consisting essentially of a silica network. Other chemical components are added to decrease its viscosity to levels suitable for melting and fiber formation. Both the physical and the chemical properties of the resultant glass are altered to varying degrees by the type and amount of modifiers.

The four main glass compositions used to create continuous fibers for reinforcement are high-alkali glass (A-glass), low-alkali or electrical-grade glass (E-glass), chemically resistant glass (ECR-glass), and high-strength glass (S-glass). Properties of glass fibers are listed in Table 1.

Table 1. Properties of glass fibers

Property	A-glass	ECR-glass	E-glass	S-glass
Density, kg/m^3	2500	2490	2540	2480
Tensile strength, GPa	3.0	3.0	3.5	4.6
Elasticity modulus, GPa		69	72	85
Coefficient of thermal expansion, 10^{-6} K^{-1}	8.6	7.2	5.0	5.6
Tensile elongation, %		2.5	2.4	2.9

Glass fibers are supplied in several basic forms, including rovings, chopped strands, mats, yarns, woven fabrics, woven rovings, nonwoven fabrics, tapes, and other special configurations.

The principal advantages of glass fibers are low cost and high strength. The disadvantages are a low modulus, poor abrasion resistance, and poor adhesion to the polymer matrix. Fiber *sizing* (containing a coupling agent) is used to improve fiber – matrix adhesion; its basic function is to form a chemical link between the glass surface and the matrix. Typically, a coupling agent consists of a silane that is adsorbed onto the glass and is capable of reactions with functional groups in the resin (→ Fibers, 5. Synthetic Inorganic, Chap. 1.5.3.). The precise mechanism of action is not known, but silane sizing performs a useful role in glass-reinforced systems involving unsaturated polyester, epoxy, vinyl ester, or thermoplastic matrices.

Glass fibers generally have good chemical resistance, are noncombustible, and do not absorb water. Substantial reduction of thermal dilatation can be achieved by the addition of glass fibers because their thermal expansion coefficient is an order of magnitude lower than that of most plastics. The useful temperature range is quite large: glass does not soften significantly until a temperature $> 400\,°C$ is reached. Glass fibers are isotropic.

2.1.2. Graphite (Carbon) Fibers (→ Composite Materials, Chap. 4.1.1.; → Fibers, 5. Synthetic Inorganic, Chap. 5.)

Graphite and carbon fibers are generally prepared by the thermal decomposition of three

fibrous organic precursors: polyacrylonitrile (PAN), rayon (cellulose), or pitch. They are available in tows containing typically 2000–10 000 untwisted individual filaments. Fiber cross sections may be circular, dog bone, or irregular, with a diameter of ca. 6–10 μm. The primary advantages of graphite over glass fibers are higher modulus, improved creep-rupture resistance, better fatigue endurance, and lower density. However, they are also characterized by a lower limit of elongation, which results in a relatively low fracture energy. Therefore, impact resistance for graphite-fiber composites is lower than for glass-fiber composites. The high strength and stiffness of graphite fibers result from a high degree of structural orientation. They are strongly anisotropic, with transverse tensile and shear moduli generally an order of magnitude lower than the corresponding axial modulus. Graphite fibers have a negative thermal expansion coefficient in the axial direction, which permits the construction of a multi-ply laminate with zero in-plane expansion. This is achieved, however, at the expense of large deformations in thickness.

Graphite fibers are usually subjected to a surface treatment which results in an increase in hydroxyl and amine groups on the fiber surface, thereby improving the adhesion between fiber and matrix and the laminate shear performance. To improve handling, a light sizing is often applied, consisting of a resin that is compatible with the designated matrix. Graphite fibers are available in various forms: continuous, chopped, woven fabric, or mat. Hybrid fabrics (made of a combination of graphite and glass or aramid fibers) are also available. The graphite fibers applicable as reinforcement are offered in high-strength, high-modulus, and ultrahigh-modulus forms. Representative properties are listed in Table 2. Other grades with intermediate properties have also been produced, and production processes continue to be improved.

2.1.3. Aramid Fibers (→ Composite Materials; → High-Performance Fibers, Chap. 3.2.1.)

Aramid (aromatic polyamide) fibers have been used in advanced composites since the early 1970s. The most widely known are Kevlar fibers. Among commercially available aramid fibers, the two types of interest for reinforcing plastics are high-modulus (Kevlar 49) and, to a lesser extent, low-modulus (Kevlar 29) materials.

Aramid fibers have stiffness and strength characteristics intermediate between glass and graphite. Their bonding to polymeric matrices is rather poor. Plasma amination of the fiber surface seems to be the most promising method for improving this property. In addition to high tensile strength, aramid fibers offer excellent toughness, outstanding heat resistance, fairly good chemical resistance, exceptional wear resistance, good frictional properties at elevated temperature, excellent tensile–tensile fatigue resistance, and a negative axial coefficient of thermal expansion.

Aramid fibers are strongly anisotropic (Table 2). Like graphite, their transverse tensile and shear moduli are about an order of magnitude lower than the axial tensile modulus. The fibers are also weak in compression, a result of their fibril microstructure, leading to use predominantly in tension-loaded construction elements. Their very low density makes them ideal for applications requiring critical weight saving, such as components for aircraft, space vehicles, missiles, and sporting goods. However, an elevated water-absorption capacity results in low values for dielectric properties. Aramid fibers are available in a variety of forms, such as continuous-filament yarns, rovings, woven fabrics, discontinuous staple, and pulp.

2.1.4. Other Continuous Fibers

Almost any organic fiber can be incorporated into a composite. For years, natural fibers such as cotton, jute, hemp, and silk have been studied as reinforcements. They are inferior to synthetics in tensile strength and modulus, but exhibit significantly higher elongation, which results in better composite damage tolerance. Low cost makes natural fibers attractive for applications with low load requirements (e.g., housing construction). A major problem, however, is their susceptibility to fungal and insect attack and to degradation by moisture.

From the category of synthetic fibers, cellulosics, polyamides, polyvinyls, polyacrylonitrile, polyethylene, and polyesters have found

Table 2. Properties of graphite (C) and aramid fibers

Property	C, high strength	C, high modulus	C, ultrahigh modulus	Aramid
Density, kg/m^3	1800	1900	2000	1440
Tensile strength, GPa	2.5	1.8	1.0 – 1.3	2.3
Young's modulus, GPa				
Longitudinal E_L	230	390	520 – 620	124
Transverse E_T	14	8	6	5
Shear, G_{LT}	10	8	7	2.6

Elongation, %	0.9	0.3	0.2	1.6

application in the preparation of composites because of their favorable contribution to impact strength, electrical properties, and chemical resistance.

2.1.5. Other Discontinuous Fibers

Some fibers, such as single-crystal whiskers and alumina and silicon carbide fibers (→ Composite Materials, Chap. 4.1.3.) lack a corresponding continuous form. They offer very high stiffness and strength, but their full potential for composites has not been realized for two reasons: (1) their original length approaches the critical length, and this low aspect ratio is further reduced during compounding and molding; (2) controlling their alignment in the product is extremely difficult.

2.2. Fillers

Fillers are used to alter certain properties of composites – including price, because they are generally much less expensive than the polymer they replace. Many fillers are available, and in a variety of shapes: fibrous, plate-like, spherical, and irregular. Because of their low aspect ratio, fillers do not improve the tensile strength of a plastic; in fact, strength is usually decreased, especially at higher filler content.

With the addition of most fillers, such as calcium carbonate, kaolin, glass (milled glass fibers, hollow and solid glass spheres, glass flakes), mica, talc, silica, wollastonite, and aluminum oxide, the composite modulus increases, cure shrinkage and thermal expansion decrease, and the heat generated during cure is reduced. Aluminum oxide trihydrate and antimony oxide act both as fillers and as fire retardants; mica and silica improve chemical resistance.

Electrically conductive fillers, such as metallic powders and carbon particles (carbon fibers, carbon black), are used to reduce the accumulation of static charge. Carbon black is used to improve the UV-radiation resistance of polyolefins. Some fillers, such as carbon black, chalk, and titanium dioxide, act as pigments. Addition of extremely fine silica particles affects the thixotrophy of liquid resins. Magnetic properties can be obtained by incorporating such magnetic mineral fillers as barium sulfate.

2.3. Polymeric Matrices (→ Composite Materials, Chap. 4.2.)

Certain physical and chemical properties of the matrix are particularly significant with respect to the properties of a composite. The main advantages conferred by polymer matrices are low cost, easy processibility, good corrosion resistance, good dielectric properties, and low density. Low strength, low stiffness, and (usually) low service temperatures, on the other hand, limit their applications. The primary functions of a matrix are to bind the reinforcing elements together, distribute the loading among them, and protect the reinforcing system; this in turn presupposes good adhesion between matrix and reinforcement. Stress-transfer capability is generally higher in thermosets than thermoplastics. However, thermosets are more difficult to

process, and they require longer molding cycles. They are also high molar mass materials, and therefore inherently relatively brittle. Their creep resistance, particularly at elevated temperature, is generally higher than that of thermoplastic matrices.

Traditionally, thermoplastics were reinforced primarily with discontinuous fibers, but high-temperature resins such as polyether ketone, polysulfone, and polyimide have made thermoplastics competitive with thermosets in the area of high-performance continuous-fiber composites as well.

The most important matrices generally are alkyds, allyl esters, epoxies, furans, melamines, phenolics, polybutadienes, polyesters, polyimides, polyurethanes, silicones, ureas, and vinyl esters. The most widely used, however, are polyesters, epoxies, and vinyl esters. For thermosets, the dominant resins are unsaturated polyesters, followed by acrylic resins, phenolic resins, epoxies, vinyl esters, and unsaturated polyester – urethane hybrids. The complete list of applicable thermoplastic matrices is more extensive, however, and includes acrylonitrile – butadiene – styrenes, acetals, acrylics, fluoropolymers, polyamides, polyamide – imide, polyarylsulfone, polycarbonates, thermoplastic polyesters, polyetherether ketone, polyethersulfones, polyethylenes, polyimides, poly(phenylene sulfides), polypropylenes, polystyrenes, polysulfones, poly(vinyl chloride), and styrene – acrylonitriles.

3. Fabrication of Polymer Composites (→ Composite Materials, Chap. 5.; → Plastics, Processing)

A typical feature of thermoset composites is that material formation and product fabrication occur simultaneously during final molding (e.g., hand lay-up, spray-up, vacuum-bag molding). In some cases, especially with thermoplastic matrix composites, compounding occurs first, and the shape is formed or molded in a second stage. However, in all cases, final composite properties are influenced significantly by processing conditions. Fabrication processes for thermosetting matrices can be classified broadly as wet forming processes and processes involving premixes or prepregs. The wet processes include hand lay-up, filament winding, pultrusion, bag molding, reinforced reaction injection molding (RRIM), and resin transfer molding (RTM). In processes using premixes, compounding is performed separately to yield bulk molding compounds (BMC), sheet molding compounds (SMC), and prepregs. The use of premixes facilitates automation.

Conventional molding and thermoforming methods, (e.g., injection molding, press molding, stamping) are used when processing thermoplastic matrix composites. However, the addition of fibers or filler particles to thermoplastics significantly alters their rheological properties and thermal conductivity, which can greatly affect molding conditions [2].

3.1. Hand Lay-up Technique

Hand lay-up is an open-mold process based on stacking the plies of reinforcing material in a special orientation and sequence, saturating them with resin, and brushing or rolling them to compact the material and remove entrapped air (Fig. 8). The hand lay-up techniqe is the simplest, most commonly used method for the manufacture of both small and large reinforced products. Typical applications include boats, radomes, pools, and tanks. This process is commonly employed with room-temperature-cure polyester resin and glass reinforcement, but

it can also be used with vinyl ester and suitable epoxy systems as well as with carbon or aramid fiber reinforcement. The reinforcement is usually in the form of chopped strand mat or woven roving. A gel coat, formed from a thixotropic pigmented resin, is widely used to produce a high surface finish.

Performance may be altered greatly by varying the resin-to-reinforcement ratio, the type of resin, the form and direction of reinforcement, and the additive content (Fig. 9).

Figure 9. A) Tensile strength and B) stiffness of various glass – polyester laminates as a function of fiber content
a) UD laminate; b) UD fabric; c) Balanced fabric; d) Chopped strand mat

3.2. Spray-up

Spray-up is a partially automated form of hand lay-up. A spray nozzle is used to propel chopped fiber and liquid resin against the mold surface until the desired thickness is reached (Fig. 10). As in hand lay-up, the quality of the product depends heavily on the skill of the operator, but labor and raw material costs are lower than in hand lay-up operations. Spray-up operations can be automated, and are more practical for fabricating large parts (e.g., boat hulls) or creating protective surface coating.

Figure 10. Schematic representation of spray-up process
a) Chopper; b) Fiber strand; c) Pressurized air; d) Resin and accelerator; e) Resin and catalyst; f) Spray nozzle

3.3. Filament Winding

Filament winding is an automated process in which continuous filament (or tape) passes through a resin bath and is then wound on a mandrel. The winding angle and placement of the reinforcement are controlled through specially designed machines in which filament feed is synchronized with mandrel rotation. The device has the capacity to vary the winding angle, filament tension, or resin content in each layer of reinforcement. The winding angle may vary from longitudinal through helical to circumferential or "hoop" (Fig. 11), which permits the design and fabrication of structural parts with a high degree of precision and very high strength. The two basic techniques for filament winding are

1) Wet winding, in which the reinforcement and matrix resin are applied during the winding stage
2) Dry winding, which uses preimpregnated reinforcement

Resin content in the laminate can be controlled more accurately with prepregs.

Figure 12. Schematic of the pultrusion process
a) Let-off; b) Impregnation bath; c) Resin control; d) Preformer die; e) Cold die section; f) Heated die section; g) Puller; h) Cut off; i) Product

Reinforcements are available in a number of forms: rovings, fabrics, tapes, mats, foils. Computer-aided design (CAD) methods are widely used to establish optimal laminate composition and fabrication conditions. Filament-wound applications include components subject to very high loads, such as pressure vessels, rocket engine cases, radomes, storage tanks, pipes, helicopter blades, and other aerospace parts.

3.4. Pultrusion

Pultrusion is a continuous processing method for obtaining composites with a constant cross section. The process consists of pulling continuous reinforcement (usually in the form of a roving or mat) through a resin bath (with removal of superfluous) into a shaping die, where the resin is subsequently cured (Fig. 12). A number of profiles, such as rods, tubes, and various structural shapes, with very high longitudinal strength and stiffness, can be produced via appropriate dies. The process is suitable for thermosetting resins (polyester, epoxy).

3.5. Bag Molding

In this process, a sheetlike reinforcement is laid up in a mold, into which the resin is introduced by spreading or coating. A flexible bag or diaphragm is used to apply pressure uniformly over one surface of the laminate. The general process can be subdivided into three basic molding methods: pressure bag, vacuum bag, and autoclave, the last of which is represented schematically in Figure 13. Heat may be applied in the form of steam in the autoclave itself or through the rigid mold. Large parts can be prepared with high-quality surface finishes. Mats, fabrics, preimpregnated forms of reinforcement, and honeycomb materials are used, and excellent adhesion to composite or sandwich core surfaces can be achieved. These features make bag molding attractive in the aerospace and high-technology areas.

Figure 13. Schematic of an autoclave molding device
a) Bag; b) Bleeder pack; c) Prepreg pack; d) Flexible dam; e) Seal; f) Mold; g) Heater; h) Pressure; i) Vacuum

3.6. Sheet Molding Compounds (SMC)

Sheet molding compounds are produced as continuous flat sheets of ready-to-mold composite material containing fibers, usually together with mineral filler, dispersed in a thermosetting resin. Chopped E-glass fibers 20 – 60 mm long are most often used as reinforcement, although

carbon or aramid fibers are also applicable, either separately or as a hybrid. Both short (discontinuous) and continuous fibers are used in SMC. Short fibers, randomly oriented in the plane of the sheet, are common in applications requiring isotropic material properties. The resin is in an uncured but highly viscous state, achieved by addition of a thickener (MgO). Curing of the resin takes place during the compression-molding operation. With the application of heat and pressure, SMC first flows into and fills the mold cavity, and then cures into a solid. Volume change on cure can be controlled by the addition of various shrinkage compensators, permitting high dimensional stability to be achieved. A schematic of an SMC device is presented in Figure 14.

Figure 14. Processing equipment for sheet molding compounds
a) Continuous-strand roving; b) Chopper; c) Chopped roving; d) Doctor blade; e) Carrier film; f) Resin–filler paste; g) Plastic carrier film; h) Compaction section; i) Take-up roll

Several types of SMC are distinguished as a function of the form of reinforcement (Fig. 15):

SMC-R	randomly oriented fibers
SMC-O	oriented SMC
SMC-CR	combination of continuous, parallel, and random fiber orientation
XMC	criss- crossed continuous fibers in a sheet
HMC	SMC with a high fiber content (no filler)

A numeral at the end of the letter designation indicates the fiber content in weight percent. For example, SMC-C (HMC) 20 R 15 contains 20 wt % of continuous parallel and 15 wt % of randomly oriented fibers.

The performance of SMC composites depends primarily on a combined effect of the amount and length of the reinforcement as well as the orientation of the reinforcement in the finished part. Many properties can be influenced favorably by the addition of fillers or other additives. SMC composites can be used to produce structural parts with complex shapes in relatively short molding times. For this reason SMC composites have found broad application in mass production, especially in the transportation industry and appliance manufacture (e.g., washing machines, refrigerators, furniture, computer housings).

Figure 15. Fiber reinforcement structures of various sheet molding compounds
A) SMC-R; B) SMC-C (HMC); C) SMC-O; D) SMC-CR; E) XMC

3.7. Thick Molding Compounds (TMC)

Thick molding compounds differ from sheet molding compounds only in thickness. This may range up to 50 mm with TMC, whereas a thickness of 3 – 6 mm is achieved with conventional SMC. Greater thickness allows chopped fibers to assume a three-dimensional random arrangement. For this reason, strength and stiffness are both lower with TMC than with SMC.

3.8. Bulk (or Dough) Molding Compounds (BMC, DMC)

BMC is prepared by mixing chopped strands with a filled polyester resin paste. For reinforcement, BMC usually contains glass fibers, with lengths ranging from 3 to 12 mm, but cellulose, cotton, and other fibrous materials can also be

used. Bulk molding compounds are manufactured by compression molding at 130 – 160 °C, depending on the resin formulation. Temperature control is extremely important in the molding process to reduce internal stresses and ensure reproducible physical properties of the product. Major markets for BMC are the transportation and appliance industries. The products are quickly molded, light, and strong, and may possess complex shapes.

3.9. Prepregs

Prepregs are materials that have been impregnated with partially cured polymer matrix. The matrix differs from that in SMC by the absence of fillers, thickening agents, and pigments. Most prepregs are based on epoxy resins. Reinforcements include glass, carbon, and aramid fibers in the form of roving, woven fabric, or mat. Continuous unidirectional fiber sheets give high-performance multilayer composites, used in high-load-bearing construction parts in the aviation and automobile industries. Prepregs are molded by hand lay-up, bag molding, or autoclave molding.

3.10. Reinforced Reaction Injection Molding (RRIM)

By reaction injection molding (RIM), two chemically reactive liquid streams are injected into a mold where polymerization and formation of the part occur. When short fibers or fillers are added, the process is referred to as reinforced reaction injection molding (RRIM). The fibers and particles must be sufficiently small to fit through the mixing head orifice (< 2 mm). Since viscosities of the essentially monomeric materials used in the RRIM process are low, the injection mixture flows into the mold under relatively low pressure and at low temperature, resulting in savings in energy and equipment.

Polyurethane-based polymers have been widely molded by RRIM. Various mineral fillers (e.g., milled glass fibers, glass fibers, glass flakes and beads, mica, wollastonite, and kaolin) are used to improve the modulus and reduce thermal expansion.

3.11. Resin Transfer Molding (RTM)

In this approach a dry reinforcement material is placed in a mold cavity before the mold is closed and resin is injected. Resin flows through the reinforcement preform, expels air in the cavity, and impregnates the reinforcement. After curing, the molded part is removed and the resin reaction may be allowed to continue to completion through postcuring. RTM resins are low-viscosity polyester epoxy and vinyl ester resins. A broad variety of reinforcements is used, such as continuous strand, cloth, woven roving, long fiber, and chopped fiber mat made of glass, aramid, or carbon.

Resin transfer molding has the potential to become an efficient, low- cost manufacturing process for the fabrication of large, integrated, high-performance products.

4. Physical and Chemical Properties

The properties of a resin – matrix composite depend on many factors, among them the properties of the constituents. The form of the reinforcement (particulate, chopped fibers, woven, etc.); its volume fraction; fiber length, distribution, and orientation; interfacial bond strength; and void content all play important roles. Many of these factors depend strongly on the nature of the fabrication process. The constituents of a composite can be combined in various ways. Therefore, determining the properties of all possible combinations is a practical impossibility. Analytical methods have been developed to permit derivation of a set of predicted properties based on the properties of the composite constituents [9–16].

The fundamental building element upon which fiber-reinforced plastics theory is based is a unidirectionally reinforced layer. Many applications involve components in the form of thin plates or shells [17]. For such structures the components are commonly assumed to be in a state of plane stress; that is, through-thickness deformations and stresses are neglected. As a result, material characteristics in the plane of the structure become of primary interest. In such a case, four elastic constants and two thermal expansion coefficients are necessary to describe the

elastic behavior of the UD layer. Like stiffness, strength is a directionally dependent parameter in composites. The strength properties of UD composites are governed by complex internal failure modes and cannot be described in a way similar to that used for elastic characteristics. Although no universally accepted law currently exists for the prediction of composite failure under arbitrary loading conditions, a number of basic strength properties do allow the structural efficiencies of composites to be evaluated. For typical fiber composites, these properties are listed in Table 3. One of the most important factors affecting composite properties is the amount of reinforcing agent present (see Fig. 9). Here the important parameter is percentage by volume, not by weight. Therefore, volume fractions of components must be used to compare composites of different composition.

As can be seen from Table 3, maximum strength and stiffness are reached in the fiber direction. To provide improved transverse properties, composites are commonly arranged in laminates such that individual layers have different orientations. In this way, the transverse properties of the laminate are enhanced at the expense of some of the potential inherent in a UD layer. An isotropic arangement of reinforcement therefore leads to much lower strength and stiffness values (Figs. 9 and 16). Composites reinforced with discontinuous fibers, such as bulk molding compounds, generally have nonuniform properties because local fiber content and orientation are difficult to control. As a result, material properties vary from point to point throughout the material, which contributes to great variation in measured characteristics, especially strength. Relatively high scatter with respect to properties is a typical feature of composites. For generalized comparisons of material weight-savings potential, the strength – density ratio is an adequate guide when loading is uniaxial. This comparison is very favorable for advanced composites (Fig. 16C). Although reinforcing fibers and fillers are elastic over a wide temperature range, the behavior of a polymer matrix is strongly temperature- and time-dependent. Such behavior can be observed in polymer – matrix composites as well, especially for matrix-governed properties [9, 16–19].

The polymer matrix also plays a dominant role in the chemical resistance of composites. One of the most important tasks of a matrix is to bind the reinforcing elements and protect them against hostile environments. To prevent fiber corrosion, the fiber volume-fraction must be kept low so that absorption and subsequent diffusion of the corrosive medium are minimized. This can be accomplished by protecting the load-carrying layer with a corrosion barrier consisting of thin, resin-rich veil liners. Chemical corrosion of composites can be prevented by careful choice of resin, reinforcement, and additives [20, 21], with the behavior of the resin being most important.

Table 3. Representative mechanical properties of several UD composites (fiber fraction 60 vol %)

Property	E-glass – polyester	E-glass – epoxy	C-HM – epoxy	C-HS – epoxy	Aramid – epoxy

ε = typical limit elongation

Of the two categories of polymers used as matrices – thermoplastics and thermosets – thermoplastics show excellent resistance to most acids, bases, and solvents. Among thermoset-based composites, polyester-based resins are generally resistant to acids and solvents, whereas epoxies are more appropriate when resistance to bases is necessary. Special resin systems, such as furans, are also available for specific chemical exposures. Phenolics and epoxies provide superior resistance to various forms of radiation [22].

Good resistance of components to environmental effects can be sustained by good manufacturing practice, appropriate material handling, and the application of consistent control standards. Prolonged storage of resins and fibers, or their exposure to high temperature, UV light, or moisture, may result in degradation and subsequent loss of corrosion resistance [23]. In addition to the effects of temperature, time, and environmental exposure, mechanical loading or fatigue also contributes to the acceleration of corrosion. Stress corrosion can be controlled by a reduction of stress levels, choice of the appropriate laminate structure, and the use of resins with high ultimate elongation [21].

Extensive literature on corrosion and environmental resistance is available from resin and fiber manufacturers, research laboratories, and several government agencies. Corrosion data banks are being developed by the manufacturers and users of composites.

5. Quality Specifications

Quality specification is accomplished by tests to determine the suitability of materials, processes, and designs for the intended applications.

The broad range of applications for reinforced plastics and their diverse properties have necessitated the development of a large number of specialized tests for evaluating mechani-

cal, optical, thermal, electrical, physical, chemical, and durability characteristics. Standard test methods and necessary equipment are described in various sources [24,25], and new testing procedures are constantly being developed [26]. Details about individual methods can be obtained from the literature [27–29]. Specific material features that must be considered when testing polymer composites include:

1) Composition of the constituents. Determination of the fractions of individual components is of prime importance.
2) Anisotropy of properties. The direction of a test (e.g., load application or heat conductivity) should be specified and recorded with the test results.
3) Inhomogeneous structure of the material. With laminates the stacking sequence of layers may play an important role under certain test conditions (e.g., bending, static as well as dynamic fatigue, environmental resistance).
4) Rheological behavior as a function of time. Loading rate and duration, frequency, and loading history must be specified carefully.
5) Relatively great variation in data. A sufficient number of samples must be examined to ensure reasonably reliable test results for the material under evaluation. Statistical analysis of the test data is necessary.
6) Influence of the fabrication process on product properties. Specimens must be prepared and tested under conditions identical to those specified for the product in question.

Tests may be destructive or nondestructive, depending on whether a sample is destroyed or degraded during the test. Nondestructive methods (e.g., ultrasonics, X-ray inspection, acoustic emission, microwave techniques) are becoming increasingly important in ensuring the integrity, reliability, and safety of composite structures [30].

6. Economic Aspects

Based on modern trends in materials technology, the reinforced plastics industry should continue to enjoy rapid growth. The trend can be seen in total shipments of reinforced plastics to the United States, which reached 1.21×10^9 t in 1988 compared to 0.91×10^9 t in 1978, for a mean annual growth rate of nearly 12 %. A similar development can be observed in Europe, where the mean annual growth rate in the 1980s was 9 %. Worldwide growth of composites during 1985 – 1988 averaged 5.5 %, and all predictions for 1990 – 1995 anticipate a growth of ca. 1.5 – 2 times the rate of growth of gross domestic product. Exceptional growth is expected [31] for reinforced plastics with the following characteristics: high performance, high performance – cost ratio, high flame resistance and low smoke index, good adhesion, and corrosion resistance.

Among composites generally, thermosets still dominate thermoplastics as matrix materials. Nevertheless, although thermosets accounted for about 75 % of the demand in the 1980s, this decreased to 70 % in 1990, and the growth in demand for thermoplastics over the first five years of the 1990 s is expected to be double that of composites in general [32].

More than 80 % of the reinforced thermoplastics market belongs to injection-molded resin matrices of nylon, thermoplastic polyesters, olefins, styrene, and polycarbonate. High-performance reinforced thermoplastics in the fastest growing material sector include polyimide, polyetherketone, polybenzimidazole, and polyarylene sulfone. This sector is expected to grow > 10 % annually [33].

The potential exists for significant further advances in composites, in contrast to the relatively minor improvements possible in such wrought sheet-type metals as steel or aluminum. Past and present performance, as well as current areas of research and development, have laid the groundwork for future growth of the composites industry. Effective exploitation of new opportunities is the key to potential large-scale market penetration and consequent profitability for reinforced plastics.

1. Introduction

Release agents are used to reduce or completely eliminate adhesion between two surfaces in contact. They are used in many industrial processes, especially in the plastics processing industry, where the use of effective release agents is indispensable to eliminate friction and ensure economic production.

The many types of release problems that can arise make the choice of a suitable release agent difficult for many users. The material of the mold surface and its physical condition are as important as the chemical constitution and physical properties of the release agent, and process parameters also play a role.

2. Physical and Chemical Background

The relationship between the constitution of release agents and their effectiveness is very complex, so that even today it is only possible to give an incomplete physical and chemical interpretation of release problems. The assessment of release agents is therefore largely subjective. Of course, it is possible to lay down some general requirements for a release agent with good functional properties. The most important of these are:

1) Formation of a smooth, continuous film
2) Good chemical resistance and low reactivity
3) Thermal stability
4) High resistance to oxidation
5) Good stability on the mold surface
6) No effect on the properties of the surface of the molded article, i.e., no blistering, streaking, discoloration, or stress cracking, and low solubility in the plastic
7) Elastic behavior of the release agent film
8) Good physiological properties and skin compatibility

Release agents usually contain several active substances together with additives such as flow improvers and wetting agents, and a carrier. The active substances should be as chemically inert as possible and must be completely free of reactive groups. However, a certain proportion of polar groups is required to give adhesion to the mold surface.

Substances used as release agents should ideally be amorphous, and should have a very low tendency to crystallize, so that they form low energy surfaces (i.e., having low surface tension).

3. Raw Materials

3.1. Waxes

Waxes (→ Waxes) in the form of solvent-based and water-based suspensions or emulsions are widely used in various release agents.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_067

For the product to be effective, it must have a small particle size. Therefore, waxes with a very low crystallizing tendency are used, so that when the suspension dries, dense, elastic films are formed. To achieve the desired properties, different types of waxes must be combined. For use in solvent-based systems, unmodified paraffins are suitable, e.g., Fischer – Tropsch waxes, microwaxes, refined paraffins from mineral oils, and synthetic polyethylene waxes. Fischer – Tropsch waxes and synthetic paraffins have good sealing properties. When used in combination with low-melting paraffins or microwaxes they can give an increase in hardness even at low addition rates. Waxes containing metallic soaps have a lower tendency to crystallize, and therefore form very fine suspensions. They are therefore used with paraffins, which have a higher crystallizing tendency.

For water-based systems, the wax materials described above are less suitable, as they lack hydrophilic groups. Here, acid and ester waxes or ethoxylated waxy alcohols are better, as they can be converted into very finely dispersed emulsions by using an emulsifier. The particle size of the solvent-based suspensions is usually in the range 1 – 10 µm, while for water-based emulsions it can be < 1 µm. Generally, the waxes used are in the solid state under conditions of use. If they are used within their softening range, a deterioration of the release and lubricating properties is usually observed. Above its melting point, the wax loses its lubricating properties and chemical resistance, and has a noticeable effect on the surface of the plastic molding. Consequently, it is unsuitable as a release agent.

Waxes often have the disadvantage that solid residues accumulate on the molds and must be removed mechanically from time to time.

3.2. Metallic Soaps

Metallic soaps (→ Metallic Soaps) have long been known as lubricants and release agents. They have better thermal stability and lubricating properties than waxes. Solutions of metallic soaps usually form very dense films. However, they have the disadvantage that they form rather hard residues on the molds. Removal of these residues is difficult and time consuming.

Metallic soaps are used in combination with paraffin waxes to produce finely dispersed suspensions. Due to their polar character, they can improve the adhesion of the release agent film to the metal surface. This is beneficial, as the film then cannot be dislodged by contact with the molding material.

Metallic soaps are important in the processing of thermoplastics and in reaction injection molding (RIM) of polyurethanes, where they act as internal lubricants and release agents.

3.3. Oils and Fats

Esters of higher fatty acids and gylcerides are used as release agents in processing many types of polymers, especially for molding processes operated below 150 °C. The polar groups present give good adhesion to the metallic molds. Fatty acid esters are also used as internal release agents and lubricants in the plastics industry. Synthetic ester oils, spindle oils, and animal oils are also used to a limited extent in the production of release agents.

3.4. Silicones

Silicones (→ Silicones) have been used in industry as release agents and lubricants for ca. 40 years. They are usually liquids of medium to high viscosity, preferably in the range 100 – 10 000 mPa · s. Very low viscosity siloxanes (< 100 mPa · s) do not possess the necessary mechanical stability. Extremely high viscosity oils ($> 10\,000$ mPa · s) can form adhesive surfaces with reduced lubricating properties. Silicones are chemically inert and have no affinity to other substances. Their most important advantage is their very good thermal stability and a viscosity that varies only slightly over a wide temperature range. Silicones are used both as aqueous emulsions and as solutions in various solvents. Owing to their low surface tension (ca. 20 mN/m) and their incompatibility with most plastics, they are among the most effective release agents. A disadvantage is that the molded articles readily pick up traces of silicone that can interfere with subsequent operations such as painting or bonding with adhesives. The silicone oil release agents can be used either alone or in combination with other substances

having release properties. Medium-viscosity silicone oils (100 – 1000 mPa · s) are especially suitable. The release properties of these linear polydimethylsiloxanes are improved by the addition of small amounts of silicone resin. Such combinations of materials often have improved barrier-layer properties, and a very effective film of release agent is produced.

Organomodified siloxanes are sometimes used as release agents and lubricants. These are mainly linear dimethylpolysiloxanes that contain organic end groups and/or side groups. Substitution by methyl groups causes partial weakening of the silicone character. For example, it is possible to obtain a water-soluble product by the chemical addition of polyoxyalkylenes. Alternatively, alkyl or ester groups can be included, giving products that have some compatibility with other polymers, and can thus be used as internal release agents and lubricants. The introduction of organic groups lowers the tendency of the siloxane to cause paint defects. Water-soluble silicones can very readily be removed from a mold after use by washing.

3.5. Polyoxyalkylenes

Polyoxyalkylenes are used as mold release agents especially in the rubber industry. They have good lubrication properties and impart an attractive finish to the vulcanized products. They can be used neat or in aqueous solution if they are water-soluble. Any residual release agent can easily be removed from the rubber articles by washing with detergent solutions.

3.6. Fluorocarbons

Fluorocarbons are used as permanent release agents in many industries. They are usually applied to the mold surfaces in the form of fluorotelomer dispersions. After the solvent has evaporated, a coherent film is produced by sintering or melting at temperatues above 265 °C.

4. Methods of Application

Release agents are generally used in the form of solutions, dispersions, or emulsions. The most widely used materials are dispersions or emulsions that can be applied to the surfaces of the mold by hand-operated or automatic spraying equipment, or by aerosol cans. The carrier liquids in sprayable release agent dispersions were at one time mainly organic solvents such as aliphatic hydrocarbons, chlorinated hydrocarbons, and fluorochlorohydrocarbons, or mixtures thereof. However, due to the increasing restrictions on emissions, and on the use of chlorofluorocarbons, aqueous release agents will be favored in future.

If the rate of evaporation of the water film is insufficient, release agent concentrates or low-solvent release agent preparations can be used. If these are of low viscosity, they can be applied by air-atomizing spray guns, which give good distribution of the active material.

The use of internal release agents has been increasing for some time. These materials, known as internal lubricants, are mixed with the plastic prior to processing. Internal lubricants have long been used in thermoplastics to reduce internal friction. Materials often used include paraffins, ester waxes, and metallic soaps, which are often soluble in the plastic. Additives are also used which have a definite solubility limit in the polymer, so that the undissolved part of the lubricant migrates to the surface, i.e., to the walls of the mold, where a very thin film is formed, thus giving both internal and external lubrication.

For reaction polymers, especially for polyurethanes, the internal release agents must have special properties. Mixing of the liquid components must lead to good emulsification of the internal release agent or lubricant. On formation of the polymer, this emulsion breaks, and the release agent separates from the polymer matrix. Sufficient release agent then migrates to the outer surface of the molding. For internal lubrication, metallic soaps and some organomodified silicones are mainly used.

5. Uses

There are many industrial processes that require release agents, so that the demand for these materials is high. Manufacturers of release agents include Th. Goldschmidt, E & P Würz, Acmos Chemische Fabriken, Tietgen & Co., Teroson

Werke, Klüber Chemie, and Wacker Chemie (Germany); Air Products & Chemical, Dow Corning, Dexter Corporation, and Chem-Trend (United States); and Rhône-Poulenc (France).

A brief review of the release agents suitable for particular production processes is given below.

5.1. Processing Polyurethane Foam

Polyurethanes are formed by the polyaddition reaction of polyhydroxy compounds with diisocyanates. The initially liquid reaction mixture used to make polyurethane foam develops strong adhesive forces to the mold. Very effective release agents must be used to enable the hardened molding to be released undamaged from the mold. Most release agents used in polyurethanes are mixtures of several waxes. The wax raw materials are dispersed at concentrations of ca. 5 – 10 % in organic solvents, preferably aliphatic hydrocarbons, or in water. A combination of microwaxes with waxes that contain metallic soaps gives very fine dispersions in organic solvents. These are used in a wide variety of polyurethane foams in the molding temperature range 30 – 70 °C. Ester or acid waxes are used in water-based release agents. Ethoxylated alcohol waxes contain water- compatible groups and can be converted to very fine emulsions by using emulsifying agents. The choice of the emulsifier for a water-based product is extremely important. It must by physiologically harmless and must not cause skin irritation; hence, nonionic emulsifiers are preferable. Water-based release agents are preferred for the production of flexible polyurethane foams. The mold temperature must be > 50 °C to evaporate the water film within a reasonable time.

Specialty silicones are also used in polyurethane release agents. Pure silicone oils, i.e., unmodified dimethylpolysiloxanes, are generally unsuitable. They exhibit strong abhesive action, but do not adhere sufficiently to the mold wall and have a strong antifoaming effect on many types of foam. In the production of highly cross-linked foams with densities > 0.3 g/cm^3, special silicone release agents are used to a limited extent. These must have a proportion of polar groups to give adhesion to the mold wall and prevent the release agent from becoming detached on contact with the molding material.

Solvent-based and water-based polyurethane release agents are best applied by air-atomizing spray equipment. This has the advantage that the air stream takes up some of the solvent or water, and the droplet dispersion is improved. Aqueous release agents are mainly used in the production of flexible foams (hot- cured foams) with mold temperatures of 100 – 150 °C. With cold- cured or high-resilience (HR) foam, problems can occur due to the lower molding temperatures (30 – 60 °C). Small amounts of residual water are thus unavoidable, and these react with isocyanate to form hard residues of insoluble, infusible, polymerized urea products. The use of water-based release agents also often leads to problems during later stages of manufacture. Contamination by the release agent gives the foam a greasy or oily surface, and interferes with the action of adhesives used to bond the moldings to other materials.

5.2. Processing Glass Fiber Reinforced Plastics

Glass fiber reinforced plastics (GRP) are usually made with unsaturated polyester or epoxy resins. The polyester resins in particular contain large amounts of reactive solvents such as styrene, and the only release agents that can be used are those that are insoluble or only slightly soluble in the monomers used in the polymerization. Moreover, the molding contracts on polymerization, and can shrink tightly onto the pattern, especially in large molds. Therefore, a good GRP release agent must also have good lubricating properties. Release agents based on hard waxes are most commonly used, usually in the form of liquids or pasty dispersions in aliphatic hydrocarbons. These also contain additives to improve lubrication, such as silicones, fats, oils, or metallic soaps. Silicone release resins are very effective for metallic molds in which epoxy resins are used. They are baked onto the surface of the mold and give extremely durable separating surfaces. Their working life can be still further increased if the mold surfaces are thinly coated with a lubricant, e.g., a silicone grease, between molding operations.

5.3. Processing Thermoplastics

For the injection molding of thermoplastics, fats, oils, and silicone oils are used as release agents, usually in the form of aerosols applied from cans. The decision whether to use a silicone or a fatty oil depends on the operating temperature. As a rough guide, silicone oils are used above 150 °C, and methylphenylsiloxanes above 250 °C. Silicone resins are very effective in the rotational molding process. They are baked on before casting is started, and enable even transparent moldings to be produced free from optical defects caused by scoring or pitting.

5.4. Processing Rubber

Rubber mixtures are formed into a wide range of articles. The release agent must be carefully formulated for each process, taking account of all relevant production conditions. In general, silicones, certain metallic soaps, polyoxyalkylenes, and surfactants (e.g., organic sulfate esters or sulfonates) are used singly or in combination. Sometimes, mineral products such as mica or talc are also used. Silicones are suitable for all vulcanization processes owing to their temperature stability and excellent release and lubricating properties, even when used in very small quantities. Polyethersiloxanes are particularly effective; they are water-soluble and can be removed from the moldings by washing.

Polyoxyalkylenes are very effective release agents for rubber. They give a velvety sheen and a dark appearance to the products, and accentuate their color. Polyoxyalkylenes have good lubricating properties. They can be made water soluble if they contain a proportion of ethylene oxide units, i.e., 30 – 50 % depending on molecular mass and degree of polymerization. Polyoxyalkylenes give almost no residues, and can be removed by a water – detergent mixture. In general, polyoxyalkylenes are used in preference to silicones if the manufacturer or end user requires silicone-free moldings. The release agents used to aid the removal of the rubber articles should, if possible, be biodegradable, and should have no harmful ecological effects. The surfactants used are mainly ethoxylated fatty alcohols, which are usually 80 % biodegradable.

The release agents are usually applied as aqueous emulsions or solutions by spraying with stationary equipment. Another common technique is to pass the preforms through a bath of release agent before molding.

5.5. Metal Industry

The mass production of metal castings requires rapid production of the necessary molds by, e.g., the Croning, hot box, or cold box processes, in which a mixture of molding sand and resin is applied to a pattern and hardened to give a mold or core. In these processes, the release agents must prevent adhesion of the resin binder to the pattern, enabling the sand mold to be slid away from it. In the Croning and hot box processes, the operating temperatures are high, and aqueous emulsions of silicones are therefore used. They have the advantage of forming a very thin coating on the pattern, thereby ensuring dimensional accuracy. In some cases, when temperatures are fairly low (< 300 °C), mineral oil emulsions can be used. Because the cold box process is operated at lower temperatures, release agents based on solvent-based dispersions or solutions are required. Silicones and hard wax dispersions are also suitable. The silicones used must be compatible with any mold coatings used.

For the injection molding of low-melting alloys, e.g., pressure die-casting of aluminum, organomodified silicones are used in combination with waxes.

5.6. Glass Industry

In the molding and shaping of glass, release agents are used both on the mold and on the metallic parts of the conveying system that transports the molten glass from the metering equipment to the mold. Although simple, cheap release agents such as mineral oils and graphite are effective, they produce large amounts of smoke and lead to the build-up of residues. Modern release agents for glass consist essentially of heat-resistant graphite-containing resins, which give hard, smooth, abrasion-resistant films. Phenolic resins, silicone resins, and some silicone – polyester resins are used.

5.7. Woodworking

Release agents are required as auxiliaries for gluing and veneering wood and wood-based materials, and for coating with synthetic resin films. When applying paper impregnated with phenolic and melamine resins, it is necessary to coat the sheet with a release agent to prevent the surface of the press from adhering to the cured surface of the resin. The release agent can be applied by spraying, spreading, or by rollers. For very large surface areas, it can be applied by a transfer process, i.e., by squeezing it out of a sheet of paper, fabric, or nonwoven soaked in the release agent. Suitable release agents include mineral oils, high-melting paraffin waxes, esters of long- chain aliphatic carboxylic acids, and sometimes silicones modified to make them paintable.

5.8. Food Industry

Release agents have been used for centuries in baking or roasting foodstuffs. Vegetable and animal fats are still used in the bakery industry, either pure or as emulsions. In recent decades, however, baking sheets and tins have been coated with silicone release coatings. Household cooking equipment such as saucepans and baking tins are coated with polytetrafluoroethylene or silicone resins to prevent food from adhering during roasting, cooking, and baking.

1. Introduction

Natural resins and balsams were known and used in the earliest human societies. The widely differing uses ranged from surface protection and decoration (e.g., Japanese lacquer, used in the third century B.C.); to preservation and mummification (Egypt), putty and adhesives, medicinal and cosmetic purposes (e.g., disinfectant sealing of wounds); to ritual and ceremonial purposes (incense). Because of industrialization and the ever-deepening knowledge of chemistry and chemical synthesis a large number of the previously important natural resins have been replaced by synthetic ones. Higher standards of living and advanced civilization would presumably make excessive demands on the world capacity of natural resins in every aspect. Nevertheless, some natural resins have retained their industrial importance and are mentioned here.

Current attempts to use nonrenewable resources as sparingly as possible have focused attention more strongly on natural (i.e., renewable) raw materials. This tendency also applies to natural resins (e.g., rosin) as a natural, renewable resource. Rosin is treated in detail in Chapter 5.

2. Systematics and Classification

For a definition of the term resins, see → Resins, Synthetic, Chap. 1.

Natural resins can be classified in several ways:

Botanical Aspects. Resins can be derived from gymnosperm (naked seeders) and from angiosperm (covered seeders); the latter are subdivided into monocotyledons (with one embryonic leaf) and dicotyledons (with two embryonic leaves).

Physical and Chemical Properties. Natural resins are also classified according to their behavior toward typical basic solvents or their melting behavior. This classification takes aspects of application technology into account. However, it does not differentiate finely enough. A classification according to occurrence seems to be more appropriate.

Occurrence. The classification into fossil, recent, and recent – fossil resins gives a basic characteristic that can then be differentiated further (e.g., according to physical and chemical properties). *Fossil resins* are those that come from plants which are extinct; some of these species are not even known for certain. Some fossil resins have undergone considerable change in their chemical structure through aging or ripening, which may have taken thousands of years. The transition from fossil to *recent – fossil* is flexible. The latter can include resins that are both found fossilized and harvested from living plants.

Recent resins are tapped (harvested) from the living plant. The plant – balsam or plant – resin relationship is clearly recognizable. Recent resins are particularly interesting from an ecological point of view because they are the only self-regenerating resins. The terms *balsam* and *turpentine* have practically the same meaning today (i.e., the resinous exudate from living trees and shrubs). Balsam or turpentine is a solution of plant-specific resins in plant-specific solvents (essential oils). Such resins can include resin acids, esters, or alcohols. The exudate is a mobile to highly viscous liquid and often contains resin particles that have already crystallized. In the course of time and as a result of other influences, the exudate has lost the liquidizing components or been chemically converted into a solid material (i.e., by autoxidation).

3. Formation – Collection

The formation of *recent resins* has been most intensively studied in the case of pine balsam. Pine balsam is a plant metabolite (plant exudate) that is formed in extract repositories in the plant. The balsam is collected in so- called resin canals, which are connected to each other lengthwise and crosswise. On opening these canals the so- called *physiological resin* flows out. Severe wounding and additional irritation (irritant resinification) lead to an increase in the number of resin canals and increased balsam production (*pathological resin flow*).

Recent – fossil and *fossil resins* are obtained from the ground by prospecting and mining. These resins often occur in secondary deposits, which are not in the original location of the plant that produced the resin. These secondary deposits may have arrived at their current position through geological faults or through transportation by water (e.g., amber or damar).

4. Individual Resins

Rosin is described in Chapter 5.

4.1. Acaroid Resin

Acaroid resin is a recent resin that is isolated from *Xanthorrhoea* species, which occur in Australia.

Appearance. Yellow and red types of acaroid resin are known, which also differ in their physical properties. Red acaroid resin is the more important.

Properties. Acid value 60 – 110 (red), 125 – 140 (yellow); saponification value 160 – 200 (red), 200 – 240 (yellow). Unlike the red type of resin, the yellow type contains cinnamic and benzoic acids, esters of *p*- coumaric acid, and xanthoresinotannol (ca. 80 %). The red type contains erythroresinotannol (ca. 85 %).

Uses. Acaroid resin is used in cosmetics, paints and coatings, and printing inks, as well as for staining wood (principally the red type) and for fireworks.

4.2. Amber

Amber is a fossil resin that originates from conifers of the tertiary period (*Pinites succinifera*). Amber was presumably formed by secondary resin flow and molded to its present form by pressure, temperature, and other influences in the course of thousands of years.

Occurrence. Amber is found at the Samland coast (Baltic coast) and the Samland peninsula (Palmnicken area). It is obtained either by collecting or fishing on the coast (sea amber) or by isolation from "blue earth," which is mined at Palmnicken (yield: ca. 1 – 2 kg/m^3 excavated material).

Appearance. Amber forms bright-yellow to brownish (amber- colored), angular or rounded pieces of different sizes that can contain inclusions.

Properties. Amber is a very hard material that is virtually insoluble in all solvents and a very good dielectric. Amber acquires a negative charge on rubbing and was therefore called *electron* in the old Greek. It decomposes at ca. 370 °C without melting. In contrast to other resins, amber contains organically bound sulfur. Its composition can vary widely. The following approximate elemental composition can be found in the literature: 78 % carbon, 9.9 % hydrogen, 11.7 % oxygen, 0.4 % sulfur, and 0.2 % ash; acid value 15 – 35, saponification value 90 – 125.

Uses. Even in antiquity amber was a very valuable commercial product and was used in jewelery by the Romans. Amber was also used for special oil varnishes in former times. For this it had to be rendered oil soluble by melting. During this treatment, losses of up to 30 % occur, and amber oil and succinic acid are formed. The term amber varnish no longer signifies that the varnish is produced from amber.

4.3. Asphaltite

Asphaltite or *gilsonite* is a fossil resin (→ Asphalt and Bitumen, Chap. 2.) that is also known as glossy pitch. It is a neutral, thermoplastic hydrocarbon resin. According to DIN 55 946 asphaltite is defined as natural asphalt with a low mineral content and great hardness [2]. This natural product is assumed to be formed from crude petroleum by evaporation of volatile components and chemical reaction (autoxidation, polymerization, etc.). Natural asphalt was known to early civilizations (Babylonians, Sumerians, ca. 3000 B.C.), where it was used as a sealing material.

Occurrence. Hard natural asphalt (asphaltite) is found in Utah/Colorado (gilsonite), Virginia, and Syria. The asphalt deposit in Utah was discovered in ca. 1860 by Samuel H. Gilson and subsequently exploited industrially. *Soft natural asphalts* (pitches) occur in Trinidad (Trinidad asphalt), the Bermudas, Cuba, Mexico, and Palestine.

Extraction. Gilsonite is found in vertical underground seams several meters wide. The depth of these seams can be up to 300 m; they can be several kilometers long. The individual seams run parallel to one another in a northwest – southeast direction.

Appearance. Gilsonite forms black, shiny pieces with conchoidal fracture; it has a dark-brown color in the pulverized state and in solution.

Properties. Gilsonite has a softening point of 145 – 195 °C (ring and ball); an acid value of ca. 2; and a density of 1.03 – 1.15 g/cm^3. It is soluble in carbon disulfide and aromatics, less soluble in aliphatics and mineral oils. Gilsonite solutions readily thicken on storage, but this tendency can be counteracted by addition of polar solvents. Lower alcohols and glycols act as pure dilution agents; gilsonite is only partially soluble in ketones and some glycol ethers. Gilsonite is compatible with many natural and synthetic resins and oils, for example, with modified rosins (e.g., rosinates, maleics, phenol-modified rosins). Gilsonite has very good wetting properties for carbon black.

The approximate elemental composition of *gilsonite* is 85 % carbon, 10 % hydrogen, 2.5 % nitrogen, 1.5 % oxygen, and 0.3 % sulfur. It contains approximately 50 – 65 % asphaltenes, 35 – 45 % resins, 1 – 5 % oils, and 0.2 % ash. With increasing softening point the proportion of asphaltene increases and that of resins and oils decreases. *Trinidad asphalt* contains ca. 82 % carbon, 10 % hydrogen, 1 % nitrogen, 6 % sulfur, and 0.5 % oxygen.

Uses. Gilsonite is an important component of various printing inks (e.g., gravure printing for illustrations and letterpress). Other uses of Gilsonite and Trinidad asphalt are in paints and coatings for buildings, industrial floor coverings, electrical insulating materials, hot-melt materials, and fillers for thermoplastics [3], [4].

4.4. Balsam of Peru

Balsam of Peru is obtained by tapping of living trees of *Myroxylon pereirae* and *M. balsamum* that occur in Central and South America.

Properties. Balsam of Peru is a viscous, yellow-brown liquid, that is nonsticky and nonstringy. It does not dry in air [5]. Balsam of Peru contains large quantities of benzyl cinnamate and benzoate. Its acid value is 60 – 80; the saponification value, 230 – 255. Balsam of Peru is used in perfumes, cosmetics, and medicine (for treating eczema).

4.5. Balsam of Tolu

Balsam of tolu is a recent resin that originates from South America (Columbia, Peru, Venezuela). It is tapped from the living trunks of *Myroxylon toluiferum*.

Properties. Balsam of tolu is a brownish, sticky, semisolid mass, which slowly becomes solid and brittle. Its acid value is 112 – 168; its saponification value 154 – 216; balsam of tolu is soluble in ether, ethanol, and alkali. In addition to resin it contains a high proportion of benzoic and cinnamic acids, their esters, and vanillin.

Figure 1. Rosin extraction from a living pine tree

Use. Balsam of tolu is used in perfumes and medicine (expectorants).

4.6. Benzoin

Benzoin resin is a recent resin; the resin forms only after wound irritation (pathological resin). It occurs in diverse Styrax species that are found in Thailand and Indonesia.

Appearance. Two commercial forms of benzoin exist: (1) *beads* or *tears* that are flat, rounded, light brown (their odor is similar to vanilla); and (2) *block benzoin*, which forms irregular brown to reddish pieces (impure).

Properties. Differences exist among Siamese, Sumatran, and Penang benzoin. Unlike Siamese benzoin, Sumatran benzoin contains cinnamic acid in addition to benzoic acid. Sumatran benzoin contains ca. 75 % alcohol-soluble components; Siamese benzoin, up to 90 %.

Uses. Benzoin is used in perfumes and cosmetics, pharmaceuticals (only Siamese benzoin), veterinary medicine, and scented candles.

4.7. Canada Balsam

Canada balsam is a recent resin that originates from *Abies balsamea* (balsam fir, *Abies canadiensis*), which occurs in Canada and the United States. It is tapped from the fir tree by making cuts under the bark. Canada balsam is a colorless to greenish, viscous, slowly solidifying liquid.

Properties. Canada balsam has an acid value of 82 – 87 and a saponification value of 89 – 100; density 0.985 – 0.995 g/cm^3; refractive index 1.5180 – 1.5210 (similar to glass); it is highly soluble in ethanol. Canada balsam belongs to the terpene hydrocarbons.

Uses. Because of the similarity of its refractive index to that of glass, Canada balsam is used mainly for optical purposes (e.g., cementing optical glass elements, embedding microscopy specimens).

4.8. Chinese or Japanese Lacquer

Chinese and Japanese lacquers are recent resins that are isolated from the lacquer tree (*Rhus vernicifera*), which occurs in China, Japan, and India. Chinese – Japanese lacquer is tapped from the living trees and by extracting parts of plants such as the branches and twigs (branch lacquer). The yields are very low.

Appearance. Chinese – Japanese lacquer is a highly viscous, gray to brown milk.

Properties. The latex dries in thin layers in air by enzymatic oxidation, which is favored by moisture, darkness, and low temperature. Daylight and higher temperature (above 30 °C) inhibit the action of the oxidase. An important component of the latex is urushiol, a derivative of catechol with an unsaturated C_{15} side chain, partially soluble in alcohol.

Uses. The well-known Japanese lacquerwork used to be carried out with the latex of the Japanese lacquer tree. It was handcrafted in the thinnest possible layers because of enzymatic oxidation. Japanese lacquer was applied to wood and leather, and could be polished to a high gloss after drying. The current term "Japanese lacquer" is a general quality specification, which has nothing to do with the classical Japanese lacquer from *Rhus vernicifera*.

4.9. Copal

Copal is the collective term for a large number of recent to recent – fossil natural resins with variable structure and very different botanical and geographical origins. Very different qualities thus exist. Copals are subdivided according to geographical criteria: kauri copal, Manila copal, West African copals (e.g., Congo, Angolan, or Cameroon copal), East African copals (e.g., Zanzibar or Madagascar copal), South American copals (e.g., Brazilian or Columbian copal). Kauri, Manila, and Congo copals are still relatively important; the other types are described in [6], [7]. Most types of copal show both an insufficient solubility in common solvents and insufficient compatibility with oils. They must therefore undergo destructive distillation to obtain cleavage products that are more compatible. These pretreated copals can be further processed e.g., by esterification.

Kauri Copal. Various types of kauri copal exist, all of which originate from the kauri spruce (*Agathis australis*) that occurs in New Zealand. They are either mined (fossil), dug from topsoil (bush copal, recent – fossil), or harvested from living trees (tree copal, recent). Kauri copal is whitish yellow, but often dark; the surface is weathered and opaque.

Physical Properties. The physical properties of kauri copal vary with the age of the resin. The acid value is 50 – 100; the saponification value, 75 – 120; and the softening point, 110 – 115 °C (Kraemer Sarnow). Kauri copal is completely soluble in higher alcohols, moderately soluble in lower alcohols, and sparingly soluble in aromatics and aliphatics. Copals used to be important raw materials for copal varnishes, which

had a high gloss, elasticity, and good weathering resistance. They were later replaced by rosin-modified phenolic resins (synthetic copals, see Section 5.5.4). Kauri copal is now used only in determining the kauri – butanol value. A low kauri – butanol value denotes a good solvent power of a solvent (high aromatic content) and is determined by titration to the cloud point of a standard solution of kauri copal in butanol against the solvent to be investigated.

Manila copal is a recent to recent – fossil resin, which is isolated from *Dammara orientalis*, which occurs in the Philippines and Indonesia. Manila copal is harvested from the living tree. An alcohol-soluble soft resin is obtained, which is insoluble in aromatics and aliphatics. A recent –fossil semihard manila copal resin (loba) is insoluble in alcohol. Manila copal needs to be melted, which involves losses of up to 20 %. It is a yellowish, often reddish to dark- colored resin. A main component is agathene dicarboxylic acid ($C_{20}H_{30}O_4$), derived from diterpenes, which is also present in kauri copal.

4.10. Damar

Damar is a recent to recent – fossil resin that is obtained from trees of the Dipterocarpaceae family.

Location – Harvesting. *Recent white damar* is tapped in Batavia, Sumatra, and Thailand, for example. *Recent – fossil brown and black damar* is mined in the East Indies and Sumatra.

White Damar. White damar forms irregular, yellowish- or reddish-white, transparent pieces of different sizes. It has the following composition: 40 % α-damar resin (alcohol soluble); 22.5 % β-damar resin (alcohol insoluble); 23.0 % damarol acid $C_{30}H_{50}O_6$ (a compound with one carboxyl and four hydroxyl groups); 2.5 % water; 3.5 % ash; 8.0 % impurities; and 0.5 % essential oils. White damar has a *mp* of ca. 80 – 90 °C (capillary), an acid value of 20 – 30, and a saponification value of 35 – 60; it is soluble in aromatics, pentanol, pentyl acetate, and carbon disulfide; moderately soluble in other alcohols, ethyl acetate, ethers, ketones, and aliphatics. It is rendered compatible with alkyd resins and oils by cooking. For nitrocellulose combinations, damar is separated from its alcohol-insoluble components (β-damar resin) by dewaxing. Here the β-damar resin components are precipitated from a solution of damar in toluene or toluene – ethyl acetate by the addition of alcohol.

Uses. Damar is still being used in combination with oils for special paints and coatings and for printing inks. The alcohol-soluble part formed during dewaxing process (Liodammar [8]) is used in nitrocellulose combinations and the alcohol-insoluble part (Lio-Resen) [8] in alkali- and acid-resistant paints and coatings.

Black and Brown Damar. Being a recent – fossil resin, black – brown damar is harder than the recent white damar. Black – brown damar has a *mp* of 160 – 180 °C (capillary); an acid value of ca. 25; and a saponification value of ca. 25. If used in combination with oils and alkyd resins, it is often melted to achieve more stable combinations. The resin is then soluble in aromatics and esters, and insoluble in alcohols.

4.11. Dragon's Blood Resin

Dragon's blood resin is a recent resin that originates from *Calamus draco* (climbing palms, also dragon or blood tree), which occurs in the East Indies and Sumatra. The resin is secreted naturally from the fruit of the climbing palm and is removed after solidification (tears). The fruit is subsequently heated in steam or extracted by boiling with water. Dragon's blood resin forms red beads, sticks, or globules. It has an *mp* of ca. 80 – 100 °C; is soluble in alcohols, ethers, and ketones; and insoluble in aliphatics. It gives bright-red films and is used for staining wood and as a colored resin for alcohol coatings and violin varnish.

4.12. Elemi

Elemi (recent) is the collective term for a group of resins derived from plants of the Burseraceae

family (*Canarium indicum*). Each type is described according to its country of origin; the most important type comes from the Philippines (Manila elemi). Elemi is tapped from the living tree; the resin appears only after the plants have been wounded (pathological resin flow) and solidifies with time. Elemi is a yellowish, also greenish, opaque, ointment-like, glutinous, sticky mass that solidifies to a brownish resin which is interspersed with crystals.

Properties. Elemi is soluble in aromatics, alcohols, esters, and carbon disulfide; and less soluble in aliphatics. Elemi has an acid value of 18 – 34, a saponification value of 25 – 60, and a softening point of ca. 80 °C. The exuding balsam contains up to 30 % essential oils [9].

Uses. Elemi was previously used as a (temporary) plasticizer in spirit varnishes and in combination with copals. Elemi oil is obtained from elemi resin by steam distillation, and is used in pharmaceuticals and in cosmetics and perfumes.

4.13. Frankincense (Olibanum)

Frankincense occurs in the United Arab Emirates, Oman, Somalia, Ethiopia, and the East Indies. The recent resin is tapped from the frankincense tree *Boswellia carterii*. The bark is intentionally wounded to obtain a milky extract that is collected after drying.

Properties. Frankincense forms pale-yellow, rounded or globular beads, as well as irregular pieces. It contains ca. 33 % boswellic acid ($C_{32}H_{52}O_4$). Frankincense has an acid value of 30 – 50 (indirect) and is moderately soluble in ethanol and alkali.

Uses. In antiquity, frankincense was known as an important fumigating resin for social and religious purposes (e.g., for funerals). It is also used in cosmetics and medicine. Besides pleasant odor, the disinfectant affect certainly plays an important role in its use. Incense was an important commercial product of the Middle East and the source of its great wealth (Arabia felix) [10]. The incense route of antiquity ran from what is now Yemen through the former kingdom of Sheba to Egypt and via Aqaba – Negev to Gaza. With time, this route by land lost its importance as the regularity of the tides and the monsoon winds were recognized and exploited.

4.14. Galbanum

Galbanum is a recent resin that is obtained from various Iranian Ferula species, e.g., *Ferula galbaniflua*. Galbanum exudes spontaneously from the bark as a milk. It is collected as a resinous gum after drying. It forms brownish to greenish-yellow beads or tears with regular rounded appearance; older resin is darker.

Properties. Galbanum contains ca. 60 – 65 % resin, 35 –40 % vegetable gum, 6 – 10 % essential oils; *mp* ca. 100 °C.

Uses. It was previously used for plasters causing skin irritation and bleeding. It is still being used in perfumery.

4.15. Labdanum

Labdanum is a recent gum resin from the leaves of various Cistacea species (rock rose), a shrub from the Mediterranean area. The resin is a highly viscous, brown mass used in perfumes as a fixative (synthetic ambra).

4.16. Mastic

Mastic is a recent resin that is harvested from the bark of *Pistacia lentiscus*. This shrub is found in the entire Mediterranean area. The resin is greenish to yellow in color and is soluble in alcohols, aromatics, and terpenes. Its acid value is 50 – 70; the saponification value, 60 – 90; *mp*, ca. 105 °C (capillary). Mastic is used in the cosmetics industry as a fixative and in solution in turpentine as a varnish for paintings. It is also used for skin- compatible plasters and adhesives (adhesives for theater make-up).

4.17. Myrrh

Myrrh is a recent tree resin from various *Commiphora* species. The resin comes from Southern Arabia and Somalia and was known in Biblical times. Myrrh is exuded from the plant as

a milk and dries to form beads, which are collected.

Properties. Myrrh forms irregular, rounded, orange-brown colored beads or lumps with lighter areas and a bitter taste [11]. A variety of types can be found, which contain up to 10 % myrrh oil (mixture of terpenes and sesquiterpenes).

Uses. Myrrh was previously used for embalming the dead and as incense. Myrrh oils and myrrh extracts are used in cosmetics as fixatives and in medicine because of their astringent action.

4.18. Sandarac

The recent resin sandarac originates from *Callitris quadrivalvis*, a cypress species that occurs in Australia, North America, and North Africa. It has a pleasant odor, is lemon yellow in color, soluble in ethanol and diethyl ether, and insoluble in water. Sandarac has a *mp* of ca. 135 °C (capillary); an acid value of 115 – 150; and a saponification value of 145 – 155. The main component is sandaracopimaric acid ($C_{20}H_{30}O_2$). Sandarac is used as a fumigant as well as for coatings (paper and leather) and for putty and tooth cement.

4.19. Shellac [11], [12], [13]

Shellac is a recent resin of animal origin that occurs in India and Thailand. It is excreted by the shell louse (*Coccus lacca* or *Laccifer lacca*) that pricks in young shoots of certain trees. The louse forms the resin from the juice of the tree and then excretes it. The word *laksha* means 100 000, because thousands of such shell lice cover the branches of the trees (hence, the term sticklac). The harvest is carried out twice a year (April – May; November – December). Sticklac contains 60 – 80 % pure shellac and 4 – 6 % shellac wax. It is scraped off the branches and twigs and freed from dirt and other foreign matter by intense washing. The material obtained is known as bead lac (85 – 90 % pure shellac, 5 – 8 % shellac wax, 2 – 3 % impurities). By melting and sieving, either sheet shellac or button lac is obtained, depending on the way in which the melt is cooled. Natural shellac contains wax components that produce mat films. It can be dewaxed by dissolving the shellac in aqueous sodium carbonate or by selective dissolving with certain solvents. A particularly light- colored product is obtained by bleaching with hypochlorite or by use of adsorption agents.

Properties. Shellac forms bright-orange to brown, shiny, transparent sheets or beads. The different qualities are Indian (hand-made) button and sheet shellac; sheet shellac machine-processed with or without wax; bleached shellac; and special shellac (water soluble). Special shellac has been pretreated with alkali or amine, and dissolves in water without requiring further additives. Shellac has a *mp* of 65 – 77 °C; an acid value of 67 – 90; and a saponification value of 190 – 260. It is soluble in alcohols, glycol ethers, acetic acid, and aqueous alkali; and insoluble in aliphatics and aromatics. Shellac attacks iron in alcoholic solution. It must therefore be handled in iron-free equipment (e.g., stainless steel, glass, ceramics). Unbleached shellac slowly loses its solubility (over years) as a result of polycondensation. Bleached shellac does so after only ca. six months and the process is accelerated by heat. Special shellac can be stored for an unlimited period. The resin contains a hydrocarboxylic acid with five hydroxyl groups, which lead to polycondensation. Graft polymerization with acrylates and styrene provides new and interesting modifications which can be used for primers, compound foils, and coatings for metals and leather.

Uses. Shellac gives resistant, flexible films with good adhesion. It is used in pharmaceuticals, foods, printing inks, watercolor painting, insulating paints polish, shoe and leather finishing, and hairdressing (hair lacquers, setting agents). Hair preparations alone account for more than 50 % of total shellac consumption. Until about 1960 the shellac gramophone record was the most important area of use for shellac. The polycondensation of shellac, which is initiated by heat (hot hardening) or in the cold by the addition of, for example, 2 % urea, (cold hardening) is widely used in the electric, electronic, and paints and coatings industry.

4.20. Styrax (Storax)

Styrax is a recent resin that is isolated from the bark of *Liquidambar orientalis* (Hamamelidaceae family), which occurs in Asia Minor. Styrax is tapped from the living tree, the resin being formed only after the tree has been wounded. Styrax is often called benzoic resin and is very aromatic, semisolid, and yellowish brown in color. It contains large quantities of cinnamic acid and its derivatives. Its acid value is ca. 105.

Uses. Styrax is used in perfumes and medicine (skin diseases).

4.21. Utah Resin [6]

Utah resin occurs in resin druses in seams of Utah coal from which it is extracted with volatile solvents.

Properties. Utah resin is a practically neutral, natural hydrocarbon resin, which has a blackish appearance as a result of colloidal carbon. It has an acid value of 2 – 3; a saponification value of 2 – 3; a softening point of 160 – 180 °C; and an OH value of 80 – 130. Utah resin is soluble in aliphatics and aromatics, and has a good compatibility with many natural and synthetic binders.

Uses. Utah resin is used in printing inks, pigment preparations, and adhesives.

4.22. Venice Turpentine (Larch Turpentine)

The recent resin venice turpentine is tapped from the tree *Larix europaea* that occurs in Europe.

Properties. Venice turpentine is a pale-green, viscous liquid that does not crystallize. Its acid value is ca. 70; its saponification value, 130 – 145. Venice turpentine contains ca. 38 % resin acid ($C_{20}H_{30}O_2$) and a diterpene alcohol ($C_{20}H_{32}O_2$).

Uses. Venice turpentine is used in perfumes and artists' paints.

5. Rosin (Colophony)

Rosin (colophony) is industrially by far the most important natural resin because, as a recent resin, it is a renewable resource, and as a result of its chemical constitution it can be modified in many different ways to give resins of widely differing compositions. The natural sources have certainly not been exhausted, and producer countries, which have been relatively unimportant until now, will presumably work their way to market in the coming years or decades. In antiquity, rosin was a well-known and commonly used resin. The name colophony is thought to be derived from the Ionic colony Colophon in Asia Minor, where it was traded in the first century A.D. Also the resin wine (retsina) is said to have been known to the Romans.

In English speaking countries the rosins processing industry has been called "naval stores." This term dates back to the 17th century when an independent rosins industry started to develop in North America as an outcome of shipbuilding. The United Kingdom did not have enough indigenous wood for construction of the many ships required. Therefore, the ships were built in the English colonies in North America where enough pine wood was available. Pine balsam, resin, wood tar, pitch etc. were produced and stored in the naval stores. Currently the term naval stores mainly refers to rosin, rosin products, and turpentine oil.

5.1. Occurrence

Gum rosin, as used commercially and industrially nowadays, is the purified and distilled rosin from the balsam of various species of pine (up to 80 different species). Their biosphere is determined by climate, weathering, soil composition, and other botanical and meteorogical factors. The most important species and their habitat are given in what follows:

Pinus	*austriaca* (black pine)	Austria
	caribaea (slash pine)	Central America, United States, Caribbean
	densiflora	Japan
	elliottii	United States [14]
	halepensis (Aleppo pine)	Greece, Portugal, Spain
	langifolia	India
	maritima (seashore pine)	France, Spain, Portugal
	massoniana (Chinese red pine)	China [15]
	mercusii	Indonesia, Burma [16], [17], Philippines
	nigra (black pine)	Austria
	oocarpa	Central America, Honduras [18]
	palustris (swamp pine, longleaf pine)	United States
	pseudostrobus	Central America, Mexico
	sylvestris (Scots pine)	Germany, Poland
	tonkinensis	China [15]
	yunnanensis	China [15]

5.2. Collection – Extraction

Three completely different methods exist for the extraction of rosin. Each of them gives a characteristic composition of the rosin.

5.2.1. Gum Rosin [*8050-09-7*]

Here the *living tree* is systematically wounded so that if the wound is sufficiently long a pathological resin flow ensues. The tree is wounded, e.g., by a number of V-shaped groovelike incisions in a herringbone pattern. Part of the sapwood is also removed so that the resin canals are cut open. Such a wound is known as a "lachte". Irritants, such as sulfuric acid, significantly increase the resin flow from the tree. Without an irritant the wound must be recut practically every other day to achieve a continuous resin flow. Besides groove cutting, wounding of the tree can also be carried out over the surface. The crude balsam, which is exuded, is collected in a tin or earthenware vessel. Small plastic bags are also often used (see Fig. 1). Rosin harvesting begins when the pine trunks have a diameter of ca. 20 cm and can then continue for about 20 – 30 years. The yield of crude balsam depends on many factors, and varies between 2 and 5 kg per tree per year [15]. The species *Pinus elliottii*, introduced into the United States in the 1980s, is said to produce up to 10 kg of crude balsam per year [14].

The crude balsam collected is then stored in a refinery, where it is covered with water to protect it from oxidation. In processing it is melted by careful warming and dissolved in a higher-boiling turpentine oil fraction. Dirt and foreign matter are removed from this free-flowing balsam solution by sedimentation; it is then filtered. Further purification involves washing with hot water, and the dilute balsam is finally subjected to continuous steam distillation, in which water and turpentine oil are removed. The average composition is ca. 70 – 75 % rosin and 20 – 25 % turpentine oil.

5.2.2. Wood Rosin [*8050-09-7*]

The stump of the pine tree is the part that is richest in resin, so developing a process for extraction of this stump resin was considered worthwhile quite early on. In the United States many stumps were left standing in past decades as a result of the clearing of large areas of pine forest for intensive wood production, so extraction of wood rosin became particularly important there. Wood rosin production utilizes stumps that have remained in the soil for 10 years or more so that only the resin-rich heartwood is still available. These types of stump are dug out and then cut up. The chips are extracted with naphtha to obtain a relatively dark resin by extraction (Wood rosin FF). The color can be removed by washing, selective extraction from a petroleum ether solution [19] with furfural, or adsorption onto bleaching clay from a naphtha solution [20]. This dark, oxidized rosin is isolated and used for lacquer applications (Vinsol R) [21]. The naphtha from the wood extraction contains turpentine oil and other substances originating from the wood.

Pine stumps contain ca. 19 % rosin, 4 % turpentine oil, 4 % petroleum ether-insoluble resins, 23 % water, and 50 % cellulose and lignin-type substances. Since pine stumps are only formed in an economically exploitable amount in the clearing of whole forests, the quantity of wood rosin available is limited and has decreased sharply in recent years.

5.2.3. Tall-Oil Rosin [*8052-10-6*] (→ Tall Oil)

The rosin that is also present in felled trees is recovered in wood digestion (sulfate process) from the black liquor. By acidification of the black liquor it is isolated as a dark, very impure resin and is then subjected to multiple distillation steps, including steam distillation. Tall-oil rosin often contains small quantities of higher fatty acids. As a result of the production process, tall-oil rosins are free of oxocarboxylic acid and thus readily soluble in aliphatics.

5.3. Composition

Rosin consists predominantly of rosin acids belonging to the terpene group. The numbering of the carbon atoms in rosin acid molecules is shown below using abietic acid as an example.

The rosin acids have the molecular formula $C_{20}H_{30}O_2$ and thus belong to the diterpenes (four isoprene units). A large number of isomeric tricyclic rosin acids exist that differ in the position of the two double bonds. The most important isomers are listed in Table 1. The acids are in equilibrium with each other. Depending on the country of origin and plant species, native rosin contains between 30 and 50 % levopimaric acid, which is the most sensitive isomer.

At > 100 to < 200 °C or upon addition of acids, levopimaric acid isomerizes to the more stable abietic acid. A shift in equilibrium in favor of levopimaric acid occurs in the Diels – Alder synthesis because levopimaric acid is removed continuously from the equilibrium by reaction with a dienophile (see Section 5.5.3). Due to the refining method, wood and tall-oil rosins are practically free of levopimaric acid. They have a high content of abietic acid, neoabietic acid, and palustric acid, and contain 15 – 30 % dehydro- and dihydroabietic acid.

5.4. Properties

Rosin has an *mp* of ca. 70 °C and is brownish to bright yellow in color. It exhibits a typical conchoidal fracture. *Gum rosin* has a slightly sweet and aromatic odor, particularly when molten. The color shade is specified by letters.

In the U.S. classification the lightest color shade is X (iodine color index ca. 12.5), followed by WW (water white, iodine color index ca. 18) and WG (window glass, iodine color index ca. 24). The dark types have the color specifications N, M, and K. The French specification recognizes still lighter types with the series AAAAAA (= 6 A) – AA (= 2 A) – AB (iodine color indices 7.5 – 12.5 – 16) and then follows the principle of the U.S. nomenclature WW – WG – N – M – K.

Typical data for rosin and its most important derivatives are given in Table 2. For gum rosin the mandatory specifications are laid down in DIN 55 935 or testing standard LY 204-74 (Peoples' Republic of China), for example. The tendency of rosin to crystallize largely depends on its purity; i.e., the fewer isomers of $C_{20}H_{30}O_2$ present, the greater is the crystallization tendency. A large number of *gum rosins* and especially *tall-oil rosins* tend to crystallize. Tall-oil rosin crystallizes especially easily because of the small number of isomers (ca. 40 % abietic acid, practically no levopimaric acid) contained and because of its content of dehydroabietic acid [22].

North American gum rosin generally has a low tendency to crystallize, which is attributed to the presence of ca. 3 % caribic acid ($C_{20}H_{30}O_3$). Honduras rosin, originating from *Pinus oocarpa*, also has a low tendency to crystallize, attributable to the high proportion of unsaponifiable substances (lower saponification value) [18]. The low crystallization tendency of *wood rosin* is due to posttreatment. The polymerized and hydrogenated types of rosin virtually do not crystallize at all.

The double bonds in the rosin acid molecules can be oxidized easily. The acids of the abietic type are prone to oxidation, but not the dextropimaric types. Oxidation results in an increase in the softening point and a decrease in the solubility in aliphatics (due to formation of oxocarboxylic acids). Modified types (i.e., rosin – maleic or rosin – phenol rosins) are less easily oxidized.

Table 1. Structure and properties of important resin acids and their contents in pine balsam, gum, and wood rosin

	Structural formula	CAS registry no.	$[\alpha_D]$*	*mp*, °C	Content in pine balsam, %	Content in gum rosin, %	Content in wood rosin, %	
Levopimaric acid			−276°	150–152	30–50	0.1–15	0.1	$C_{20}H_{30}O_2$ Upon heating to > 100°C these acids are in equilibrium with one another; abietic acid disproportionates upon heating to > 200 °C
Neoabietic acid			+159°	167–169	15–20	10–60	ca. 10	
Palustric acid			+ 72°	162–167	ca. 10	ca. 20	ca. 12	
Abietic acid		[*514-10-3*]	−106°	173–175	5–10	10–40	ca. 30	
Dehydroabietic acid			+ 63°	171–173	1	1–10	5–20	$C_{20}H_{28}O_2$
Tetrahydroabietic acid					1	1	14	$C_{20}H_{34}O_2$
Dihydroabietic acid		[*27216-04-2*]			4	4	14	$C_{20}H_{32}O_2$ (isomers)
Dextropimaric acid			+75°	217–219	8	8	8	$C_{20}H_{30}O_2$ stable
Isodextropimaric acid			0°	162–164	8	8	8	$C_{20}H_{30}O_2$ stable

* 1% solution in ethanol.

Table 2. Physical properties of the most important rosin types and derivatives

Type	Acid number	*mp* ∗, °C	Saponification number	Unsaponifiable residue
Gum rosin	ca. 170	ca. 85/75 – 65	ca. 170	6 – 8
Tall-oil rosin	160	78/68 – 58	177	ca. 12
Wood rosin	160	73 ∗∗	168	6 – 8
Disproportionated rosin	155	70 ∗∗	160	ca. 10
Polymeric rosin (40 % dimeric acid)	154	100/90 – 80	158	7 – 9
Polymeric rosin (60 % dimeric acid)	154	115/105 – 95	158	7 – 9
Polymeric rosin (80 % dimeric acid)	142	140/130 – 120	155	7 – 9
Hydrogenated rosin	161	68 ∗∗	167	ca. 9

∗ *mp* according to Kofler, unless otherwise noted.
∗∗ Ring and ball (corresponds approximately to the highest value according to Kofler in this temperature range).

Polymerized and hydrogenated rosin types exhibit the best resistance to oxidation.

5.5. Modified Rosin Types

Because of the structure of abietic acid and its isomers, rosin can undergo a large number of reactions to form products with very different physical properties. These products are used in varying applications [23].

5.5.1. Rosinates

The production of complex rosin soaps and other salts of abietic acid is one of the oldest modifications of rosin that is still in use today.

In terms of quantity the *alkali soaps* of abietic acid form the largest proportion of industrial rosinates. They are used in the paper industry for paper sizing. Rosin is digested with a substoichiometric quantity of soda or sodium hydroxide solution. A mixture of alkali soaps and free acid is obtained (free-rosin size). The emulsion is stabilized with protective colloids (casein, animal size). This rosin size is added to the pulp stock in the Hollander.

Rosin pretreated with formaldehyde, rosin – maleic acid adducts, and for special papers, hydrogenated rosin are also used for the production of rosin soaps. Alkali soaps of disproportionated rosin are used in large quantities as emulsifiers in the rubber industry.

Alkaline-earth (Ca, Mg) and are important for the formulation of printing inks, principally for gravure and screen printing. *Calcium rosinate* is the oldest and most important rosin. The formation of calcium rosinates from polymerized rosin leads to a higher-melting lime rosin. If complex rosinates are used, rosins with melting points up to 200 °C are obtained. Even the viscosity (mostly in toluene) can be influenced over wide areas.

Calcium rosinates are currently produced primarily in a melt process. The alkaline-earth component is added as the oxide, hydroxide, or acetate in portions to the molten rosin at > 200 °C, giving rise to vigorous reaction.

Zinc rosinates are produced predominantly from polymerized rosin because, with native rosin, undesirable thickening or even gel formation can occur during production. Areas of use include printing inks, adhesives, and paints and coatings.

Composed rosinates (e.g., Ca – Zn or Zn – Mg) are often used to achieve special properties.

The *heavy-metal rosinates*, such as cobalt, lead, manganese, or copper rosinates can be produced either in a melt process or in solution. The latter generally gives purer products. An aqueous solution of the metal salt is stirred into a warm aqueous solution of sodium rosinate so that the desired metal rosinate is precipitated. Various heavy-metal rosinates are still used today in specialized areas (ceramic dyes, linoleum production, etc.).

5.5.2. Rosin Esters

The esterification of abietic acid is slower than that of fatty acids because of the tertiary acid group in the molecule. Temperatures of > 200 °C (up to 275 °C) and long reaction times are necessary for the esterification. Nevertheless

the reaction goes to practically 100 % completion. Within a reaction time of 16 – 18 h the acid value decreases to < 10, or 10 – 20, depending on the raw material used. The most common and oldest rosin ester is the glycerol ester of native rosin. If reaction conditions are properly maintained, acid values of < 10 and very good solubility in aromatics, aliphatics, esters, and ketones and good compatibility with the common binding agents and elastomers (for adhesives) are achieved. The reaction proceeds, via glyceryl diabietate as intermediate, to diglyceryl abietyl ether, which has very good properties (compatibility, solubility, water resistance). Instead of the abietyl ether, glyceryl triabietate can be formed, which falls markedly short in terms of the above properties. The relatively harsh reaction conditions (temperature – time) also give rise to the formation of dehydro- and dihydroabietic acid (disproportionation reactions), which improve the general properties.

Methanol, glycols, and polyhydric alcohols such as glycerol and pentaerythritol are commonly used as esterification agents. Esterification with methanol either requires pressure or must be carried out with dimethyl sulfate or chloromethane [24]. The methyl and glycyl esters are syrupy liquids. Besides the esters of native rosin (gum rosin, wood rosin, and tall-oil rosin), esters of polymerized – dimerized, hydrogenated, and disproportionated rosin can be found. The hardest rosin ester is the pentaester of dimerized rosin (*mp* ca. 160 °C).

Uses. Rosin esters show a very good compatibility with many elastomers, such as ethylene – vinyl acetate, styrene – isoprene – styrene copolymer (SIS), and styrene – butadiene – styrene copolymer (SBS), natural rubber, chloroprene rubber, etc. The solubility in a large number of solvents (including aliphatics) is very good. Their main area of use is currently as tackifiers in adhesive formulations (solvent-containing adhesives, hot-melt adhesives, dispersion adhesives). Soft rosins are used successfully in dispersion adhesives because they are readily emulsified. Rosin esters are used in formulations of paints and coatings and printing inks because of their good compatibility with nitrocellulose. Certain limitations in nitrocellulose compatibility can be expected with pentaesters, however. Rosin esters with high melting point can also be used as complementary rosins in coating formulations with alkyd rosins, where they improve the body, gloss, and drying time. Deodorized glycerol ester is a component of chewing gum but has to meet definite purity specifications [25].

5.5.3. Maleic Acid Adducts (Maleics)

Because of its conjugated double bonds, levopimaric acid can, as a typical diene, undergo Diels – Alder reactions. Frequently used dienophiles are maleic acid or maleic anhydride, and fumaric acid. Besides these two compounds, acrylic acid and its derivatives are also important industrially. Above 150 °C the isomers which are in equilibrium with levopimaric acid (abietic acid, palustric acid, and neoabietic acid) undergo Diels – Alder reaction. The reaction is exothermic and gives tricarboxylic acids (high acid value, higher melting point). Theoretically, ca. 25 % maleic anhydride can be added to rosin, but in practice much smaller quantities are generally used. The maleic rosins, which are frequently used industrially, are mixed esters from native rosin and Diels – Alder adducts.

All maleic rosins are characterized by their light colors, improved stability toward oxidation, lightfastness, and good pigment wetting properties. They are compatible with many binding agents.

Three different groups of maleic and fumaric acid adducts exist with differing features (see Table 3).

Unesterified adducts are used, for example, in printing inks (moisture set) and in paper size production.

Partially esterified maleic rosins are particularly important because of their high solubility in alcohol and water (after neutralization), their very good compatibility with nitrocellulose, and the broad melting-point range possible. Melting points between ca. 50 and 180 °C are possible, and can be influenced by the degree of adduct formation and the choice of special esterification components. The *areas of use* involve mainly nitrocellulose combinations and aqueous systems (e.g., paints and coatings and printing inks; for the latter, flexographic printing with alcohol and water). Ammonia or a range of amines and ami-

Table 3. Different types of maleic rosins ∗ and their basic features

Type	Acid number	*mp*, °C	Solubility	Compatibility
Unesterified	280 – 310	125 – 160	alcohol, ester	nitrocellulose
Slightly esterified	180 – 205	50 – 70	alcohol, ester, water	nitrocellulose
Slightly esterified	110 – 130	120 – 160	alcohol, ester, water	nitrocellulose
Higher esterified	60 – 100	120 – 160	alcohol, ester	nitrocellulose
Completely esterified	20 – 50	100 – 160	ester	nitrocellulose

∗ Product specifications of Lackharzwerke Robert Kraemer, Bremen, Germany.

no alcohols can be used for neutralization [26], [27].

Even nonneutralized alcoholic rosin solutions show good water tolerance (ca. 30 % based on alcohol in a solution with 30 % solid material). More highly esterified maleic rosins (acid value ≥ 60) lose their water solubility but are completely soluble in alcohol.

Completely esterified rosins are insoluble or only sparingly soluble in alcohols but are readily soluble in esters, ketones, and aromatics. The main *areas of use* are combinations with nitrocellulose (coatings, special gravure printing) but also with oils and alkyd rosins. Rosins with a high content of maleate groups are no longer oil compatible; their nitrocellulose combinations must contain suitable plasticizers (e.g., phthalates, nondrying alkyd rosins, or liquid rosin ester rosins).

5.5.4. Rosin-Modified Phenolic Rosins [28], [29] (→ Phenolic Rosins→ Phenolic Rosins, Chap. 4.3.)

Although the term rosin-modified phenolic rosins has become established, phenol-modified rosins would be more appropriate because rosin predominates in quantity and character. These rosins were also known as synthetic copals because they were able to replace natural copals on account of their technological advantages.

The most common phenols used in the modification of rosin are 4-*tert*-butylphenol and 4,4′-diphenylolpropane (bisphenol A). Through this choice and the wide variation in the ratio of phenol to formaldehyde, a large number of rosin-modified phenolic rosins are accessible. The number is increased still further by the fact that polymerized – dimerized rosins can also undergo this reaction.

The melting point of this group of rosins is in the range of 100 – 180 °C; the acid value varies between 10 and 40. Special types with higher acid values (up to 140) also exhibit good solubility in alcohols. Rosin-modified phenolic rosins can be combined with many alkyd rosins and also show good oil compatibility. They accelerate the drying of coatings, increase the resistance to water and chemicals, and improve the gloss. Rosin-modified phenolic rosins are used in alkyd coatings, printing inks, especially for gravure and offset printing.

5.5.5. Polymerized – Dimerized Rosins [30], [31]

The double bonds present in abietic acid can undergo polymerization. Strictly speaking this is a dimerization, so the expression dimerized rosin would be more appropriate. In practice, however, only rosins with more than 50 % dimeric acid are called dimerized rosins.

The polymerization – dimerization can be carried out in solution at ambient temperature or in the melt in the presence of catalysts such as sulfur, *p*-toluenesulfonic acid, boron trifluoride, zinc chloride, and concentrated sulfuric acid. Disproportionation of the molecule can occur as a side reaction. The common polymerized rosins contain ca. 40, 60, or 80 % dimeric acid. The melting point of this series increases from 70 °C (native rosin) to 100, 120, and 140 °C. All polymerized rosins have a low tendency to crystallize, a high oxidation stability, and an excellent compatibility with many other binding agents and elastomers. The acid value is not affected by polymerization so this group of rosins can undergo typical modification reactions (e.g., rosinate formation, esterification). Since polymerized rosin contains considerable proportions

of native rosin, addition reactions with maleic anhydride or phenol resol can also be carried out. Polymerized rosins and their modifications are used in formulations where enhanced stability or rosins with higher melting point are required.

5.5.6. Hydrogenated Rosins [32], [33]

The double bonds of abietic acid, which are prone to oxidation and are attacked in the presence of light, can be removed by hydrogenation. This route is considerably more expensive than the formation of dimerized rosins, but leads to still more stable rosins. Complete hydrogenation is not necessary; removal of only one of the double bonds per molecule is sufficient. Both the completely and the partially hydrogenated qualities are, however, available industrially. Hydrogenation is performed in the melt at up to 300 °C, up to 35 MPa, and in the presence of noble metal, Raney nickel, or Ni – Al alloy catalysts. The choice of suitable catalysts and the appropriate reaction conditions are particularly important, because otherwise reduction to abietyl alcohol (see Section 5.5.8) or decarboxylation can occur. Partial hydrogenation occurs much more readily and rapidly than complete hydrogenation. If the reaction is carried out properly the carboxyl group remains unchanged and can undergo esterification or rosinate formation. Hydrogenated rosins are used, for example, as particularly oxidation-resistant and lightfast tackifiers in adhesives. The alkali salts are used in the paper industry for special papers and as emulsifiers in emulsion polymerization.

5.5.7. Disproportionated Rosins [34]

Rosin acids with conjugated double bonds such as abietic acid or palustric acid can be disproportionated catalytically to dehydro- and dihydroabietic acids, and tetrahydroabietic acid. Catalysts for this reaction are Pd/charcoal, iodine, sulfur, and organic disulfides. The slightly exothermic reaction starts at ca. 250 °C. With Pd as catalyst 50 – 60 % of dehydroabietic acid and 25 – 35 % of dihydroabietic and dihydropimaric acid together with traces of tetrahydroabietic acid are formed. Decarboxylation leads to ca. 10 % of various neutral compounds.

Disproportionated rosins are highly stable toward oxidation. They are used widely in the form of their alkali soaps as emulsifiers in emulsion polymerization processes for the production of synthetic rubbers and latices. Other application areas are pigments and adhesives.

5.5.8. Rosin Alcohols

In the presence of appropriate catalysts and under harsh conditions the hydrogenation of abietic acid can result in reduction of the carboxyl group to give a rosin alcohol. Since disproportionation occurs simultaneously, a mixture of dehydro-, dihydro-, and tetrahydroabietyl alcohols ("hydroabietyl alcohol") is formed. Heavy metals and copper chromite are also used as catalysts. Industrially, hydrogenation of the methyl ester of rosin is carried out at up to 300 °C and high pressure. Rosin alcohols are light, sticky rosins with good stability toward oxidation. They are used in adhesives as tackifiers and as plasticizers in paints, coatings, adhesives, and plastics. Like many tackifying soft rosins hydroabietyl alcohol also improves the adhesion of a film (coating, printing ink, adhesive) on a base with poor adhesion. The alcohol group can undergo further reactions such as etherification or esterification.

5.5.9. Rosin Acid Nitrile, Rosin Amine

Rosin acid nitrile is formed in the reaction of rosin with ammonia at ca. 300 °C in the presence of catalysts. The main component of rosin acid nitrile is dehydroabietyl nitrile. This is a viscous oil with an acid value of ca. 10 – 15. Industrially, rosin acid nitrile is converted into the amine by hydrogenation under pressure. The resulting dehydroabietylamine is a viscous liquid with an amine content of ca. 92 %. The amino group can undergo many subsequent reactions (e.g., salt formation with inorganic or organic acids, or reaction with polyoxyethylene). Rosin acid amine and its reaction products are used to combat fungi, bacteria, and algae; as corrosion inhibitors in water systems; or as process materials in ore flotation and pharmaceuticals.

5.6. Economic Aspects [35]

Total annual production of rosin is about 1.2×10^6 t/a worldwide in 1995. Of this it is estimated that almost 720 000 t/a, or 60 %, is gum rosin, most of the remainder, about 35 %, is tall oil rosin and the rest is wood rosin.

The naval stores industry is complex and ever-changing. In the early part of the century, gum rosin production was dominant. Wood rosin production, involving the uprooting and extraction of old pine stumps, developed in those countries with large areas of raw materials, such as the United States and the former Soviet Union. Production in the United States peaked during the 1950s and has since declined to a low level. The recovery of tall oil rosin as byproduct of chemical pulping of pine chips also began during the 1950s.

As labor in the more industrialized countries has become more expensive, gum rosin production has declined in European countries. Statistical figures for 1991 to 1993 show that the focus of production of gum rosin today is Southeast Asia. Chinese production accounts for 430 000 t/a (about 60 %) of the total annual production of gum rosin and Indonesia for a further 70 000 t/a. In the last decade the production in Portugal dropped from 100 000 t/a to 20 000 t/a. Production in Russia is estimated to be at a level of some 65 000 t/a. Brazil produces about 45 000 t/a and Mexico and Argentina some 20 000 t/a. All other countries auch as Guatemala, Honduras, Venezuela, India, Vietnam, France, Spain, Greece, or Poland have only a small production mainly for domestic comsumption.

Leading producers of tall oil rosin are the United States and Canada with some 275 000 t/a, followed by the Scandinavian countries with about 50 000 t/a.

5.7. Toxicology and Food Regulations

(see also, → Resins, Synthetic, Chap. 4.)

Native rosin can be regarded as harmless and nontoxic. This also applies to many of its derivatives and modified rosins. Rosin esters are used, for example, in chewing gum, and rosin wine (retsina) is considered to be particularly beneficial. About a hundred workers, who were in daily contact with a large number of modified rosins, have been checked over a period of more than 25 years. No damaging effects on health could be established. Allergic reactions of certain people cannot, however, be ruled out. There is no evidence that allergy initiation can be attributed to any toxicological properties of rosin.

The legal licensing of modified rosins (rosinates, rosin esters, maleics, and modified phenolic rosins) in foods is governed by a large number of national regulations, which are also recognized internationally. The most important regulations are those of the FDA [36], but many regulations of the BGA are observed in other countries [25], [37]. Principally most of the aforementioned modified rosins are permitted in foods. However, certain restrictions or exceptions must be taken into consideration.

5.8. Analysis

Determination of the general and important physical data for rosins is laid down in many nationally and internationally recognized test regulations (e.g., DIN, ASTM). Special test methods for rosins include the following:

5.8.1. Melting-Point Determination

The classical method for melting-point, determination, the capillary method, is often not suitable for the rapid, routine testing of rosins, which can be soft or slightly sticky. In rosin chemistry the *ring and ball* method (DIN 53 784, ASTM D 2398) is used successfully and gives readily reproducible values. Another method in use is the *drop points*method according to Ubbelohde (DIN 51801).

5.8.2. Crystallization Test (Acetone Test)

The crystallization behavior of rosins in acetone gives an important indication of their quality and origin. Tall-oil rosins crystallize sponta-neously; gum rosins, with a few exceptions, within an hour; and polymerized and hydrogenated rosins, not at all. The rosin is coarsely ground in a mortar, and the rosin pieces are freed from dust in a sieve; 10 g of this dust-free substance is weighed

into a test tube (200×30 mm) and covered with 10 mL of acetone. The sample is allowed to stand without stirring or shaking. The time interval after which crystallization begins (on the rosin pieces or on the base of the tube) is determined [27].

5.8.3. Other Methods

All types of rosins (modified and unmodified) can be analyzed easily by IR spectroscopy [38]. Rosin and the different rosin acids can be identified by means of UV spectroscopy and capillary gas chromatography.

A basic identification of rosin is also possible by means of the *Storch–Morawski color reaction*. This and other color reactions of colophony are described in detail in [6]. Various types of rosin can also be differentiated by their optical rotation. Disproportionated and hydrogenated rosins, for example, show a positive rotation, and polymerized–dimerized rosin a negative one.

When a mixture of rosin acid and fatty acids is to be separated the rapid and quantitative formation of the methyl ester of the fatty acid can be advantageously utilized, whereas rosin, with its tertiary carboxyl group, does not react under these conditions [39], [40].

Other methods for the determination of special physical or technical data are described by rosin producers in their leaflets.

1. Definition

The term "resin" is a versatile expression that is not sharply defined. Originally, the term was applied to low molecular mass natural products, which were usually defined as yellowish to brown- colored, transparent to opaque, soft to brittle, easily fusible, tacky and noncrystallizable materials that are soluble in most common organic solvents and virtually insoluble in water. With the development of the chemical industry, the term resin has also been applied to synthetic

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_089

materials that are used as substitutes for natural resins, or to materials with similar physical properties. In the international standards ISO 472 (Plastics – Vocabulary) and ISO 4618/3 (Paints and Varnishes – Vocabulary – Part 3: Terminology of Resins), resins are defined similarly, i.e., as solid, semisolid, or pseudosolid organic materials that have an indefinite and often high relative molecular mass, and generally soften or melt over a range of temperatures on heating. Very often, the term resin is also used to designate any polymer that is a basic material for plastics (e.g., polyethylene resin, → Plastics, General Survey). In the German standard DIN 55 958, resin ("Harz") is defined as a collective term for solid to liquid organic products. Their molecular mass distribution can vary within wide limits. Resins include a large variety of organic substances of different chemical composition, but with many similar physical properties.

Generally, resins are products with medium molecular mass. Their average molecular mass does not exceed 10 000 and, in most cases, is even lower. Resins have an amorphous and often complex structure. They do not exhibit a sharp melting point, but like every amorphous polymeric system, resins have a glass transition temperature and are characterized by their softening point, which denotes the transition temperature from a pseudosolid to a plastic state on heating.

Resins can be subdivided into natural and synthetic resins.

Natural Resins. In ISO 4618/3, natural resins are defined as resins of vegetable or animal origin. The term includes rosins (gum, wood, or tall-oil rosins from tree and plant exudates; wood extracts; or byproducts from paper manufacturing), fossil resins such as amber; mined resins such as asphaltite; shellac as secretion product from an insect; and their main derivatives.

Synthetic Resins. In ISO 4618/3, synthetic resins are defined as resins resulting from controlled chemical reactions such as polyaddition or polycondensation between well-defined reactants that do not themselves have the characteristics of resins. Synthetic resins are also obtained by polymerization (ISO 472) of unsaturated monomers. This term includes two subgroups:

1) Hydrocarbon resins, i.e., synthetic resins from coal tar, petroleum, and turpentine streams, produced by polymerization. These resins are used like natural ones, e.g., in combination with other polymers to impart special properties such as tack, flow, and hardness to a material.
2) Synthetic resins obtained mainly by addition polymerization and polycondensation, which are intermediates in the synthesis of higher molecular mass plastics.

2. Hydrocarbon Resins

2.1. Classification

The term hydrocarbon resin is generally applied to low molecular mass thermoplastic polymers that are composed mainly of carbon and hydrogen. With respect to their origin, hydrocarbon resins can be classified in four main groups:

1) Petroleum hydrocarbon resins, derived from cracked petroleum distillates
2) Indene – coumarone resins, based on coal-tar oils
3) Terpene resins from turpentine fractions
4) Resins from pure monomers

The oldest family of hydrocarbon resins is the indene – coumarone resins, discovered by Krämer and Spilker in 1890 and produced on an industrial scale since about 1910. In the mid-1930s the terpene resins were developed, which are based on byproducts of rosin extraction. Only in the 1940s did the petroleum resins become known, initiated by the rapid development of the petrochemical industry. These resins established their position as the most important group of these products. Resins from pure monomers came onto the market in the mid-1970s.

2.2. Raw Materials

The main sources of raw materials for the chemical industry are pyrolysis processes [e.g., of coal in coke ovens and, to a larger extent, of petroleum fractions in steam crackers (→ Ethylene, Chap. 5.1.)].

Pyrolysis of coal gives high-temperature coal tar as byproduct of coke production. The most important products are:

Coke	ca. 75 wt %
Coke-oven gas	13 wt %
Crude tar	3 wt %
Crude benzole	1 wt %

The first stage of coal-tar distillation gives water and the coal-tar light oil. The latter and the following carbolic oil fraction contain the aromatic unsaturated compounds that are useful in indene – coumarone resin production [4].

The pyrolysis of naphtha fractions can generate the following products and quantities, depending on the origin of the naphtha and the cracking conditions:

Hydrogen	1.0 wt %
Methane-rich gas	15.0 wt %
Ethylene	28.0 wt %
Ethane	3.5 wt %
Propene	14.0 wt %
C_4 fraction	9.0 wt %
C_5 fraction	3.0 wt %
Benzene	7.5 wt %
C_6 fraction	1.0 wt %
Toluene	5.0 wt %
C_8 aromatics	3.0 wt %
C_9 aromatics	3.5 wt %
Residual oil	5.5 wt %

The following crude feeds are used as starting materials in the production of hydrocarbon resins:

1) C_5 streams that contain linear and cyclic olefins and diolefins as resin formers are used for the production of aliphatic hydrocarbon resins
2) $C_8 - C_{10}$ streams containing styrenes, indenes, and dicyclopentadiene (DCPD) are used for the production of aromatic hydrocarbon resins

The composition of the feedstock is very important for the properties of the final resin. It affects color, degree of unsaturation, softening point, molecular mass distribution, solubility, and compatibility of the product. The crude cuts can be processed in various ways to give suitable raw materials for the manufacture of different resin types.

2.2.1. Indene – Coumarone Feedstocks

Coal-tar light oil and carbolic oil, containing aromatic resin formers such as styrene, α-methylstyrene, vinyltoluenes, indene, methylindenes, and coumarone, are treated to remove phenols and pyridine bases by extraction. Further treatment steps to improve resin color and properties are generally applied [5]. A typical composition of an indene – coumarone resin feedstock is as follows:

Styrene	2.0 wt %
α-Methylstyrene	1.0 wt %
Alkylbenzenes	30.0 wt %
Vinyltoluenes	4.0 wt %
Dicyclopentadiene	5.0 wt %
Coumarone	7.0 wt %
Indene	48.0 wt %
Methylcoumarones and methylindenes	3.0 wt %

2.2.2. Petroleum Resin Feedstocks

C_5 Streams. C_5 streams from depentanizer effluents consist of olefins and diolefins such as isoamylene, isoprene, piperylene, and cyclopentadiene, together with C_5 paraffins. A straight depentanizer C_5 stream gives only poor resin quality. The resulting resin is highly susceptible to oxidation. Lowering the cyclopentadiene content by heat soaking and subsequent distillation improves product quality. Modern C_5 resins are made from distilled concentrated piperylene streams that are obtained in isoprene recovery. Special qualities are produced from extractively distilled piperylene concentrates. Some typical compositions are given in Table 1.

The diolefin/monoolefin ratio and the nature of monoolefins present in the feedstock affect the overall course of the polymerization process and the molecular mass distribution of the final resin and are therefore carefully controlled.

C_8/C_9 Streams are obtained from a special separate downstream column. The BTX (benzene, toluene, xylenes) fraction is drawn off as the top product, and a C_8/C_9 material is obtained as a sidestream or residue, depending on the process. This material contains high-boiling unsaturated benzene homo-

Table 1. Typical composition (weight percent) of C_5 resin feeds from steam cracking

Raw materials	Straight	Distilled concentrate	Extractive distillation concentrate
Cyclo- and dicyclopentadiene	19.0	7.5	2.0
Isoprene	30.0	8.0	0.5
Piperylene	14.0	38.0	69.0
Pentenes	15.0	12.5	0.5
Pentanes	11.0	15.0	2.0
Cyclopentene	2.0	8.5	18.0
Other hydrocarbons	9.0	10.5	8.0

logues, such as styrene, α-methylstyrene, vinyltoluenes, indene, and methylindenes, together with some dicyclopentadiene that arises from the depentanizer bottoms by dimerization of cyclopentadiene. Suitable C_8/C_9 streams can be pretreated to improve resin color and properties. A typical composition is given below:

Styrene	2.0 wt %
α-Methylstyrene	4.0 wt %
Vinyltoluenes	20.0 wt %
DCPD and codimers	6.0 wt %
Indene	20.0 wt %
Methylindenes	5.0 wt %
Naphthalene	5.0 wt %
Other nonreactive aromatics	38.0 wt %

Dicyclopentadiene concentrates are generated in the heat-soaking of depentanizer effluents and subsequent distillation of C_5 fractions. Besides dicyclopentadiene, such streams may contain codimers of cyclopentadiene with other dienes, such as butadiene or isoprene, and methyl derivatives of dicyclopentadiene. Dicyclopentadiene concentration may vary from high (90 – 95 %) through medium (70 – 80 %) to relatively low. A typical composition is given below:

Dicyclopentadiene	65 – 98 wt %
Codimers	2 – 35 wt %
Benzene	1 wt %
Sulfur	150 ppm

C_4 streams contain mainly isobutenes. After removal of butadiene, a suitable feedstock for resin production may have the following composition:

1-Butene	ca. 10 wt %
cis- and *trans*-2-butene	10 – 15 wt %
Isobutene	15 – 30 wt % or more
n-butane	ca. 30 wt %
Isobutane	ca. 30 wt %
C_{5+} components	balance

Pure Commercial Monomers. The pure commercial monomers styrene, α-methylstyrene, and vinyltoluenes are used individually, as blends, or together with terpenes or other selected unsaturated aliphatic compounds in resin manufacture. Styrene is produced in large quantities by alkylation of benzene and subsequent dehydrogenation. Its main use is in the manufacture of polystyrene. α-Methylstyrene is a byproduct of the large-scale production of phenol. Vinyltoluenes are produced in smaller quantities by alkylation of toluene, followed by dehydrogenation. Commercial vinyltoluene is a mixture of 64.5 % *m*- and 35.5 % *p*-vinyltoluene.

Terpene Monomers. The raw material for the production of terpene resins is based on natural terpene monomers that are obtained from various sources such as naval stores (gum and wood turpentine) and kraft paper production (tall-oil turpentine). Citrus terpenes, obtained by extraction from orange peel in the production of orange juice, are also used as raw materials. The most important terpenes for resin manufacture are α-pinene, β-pinene, and dipentene (*dl*-limonene). Typical compositions of terpene oils are listed in Table 2.

Table 2. Typical compositions of terpene oils (in wt %)

	Gum turpentine	Wood turpentine	Tall-oil turpentine
α-Pinene	58 – 65	ca. 80	60 – 70
β-Pinene	23 – 35	0 – 2	20 – 25
Camphene		4 – 8	
Other terpenes	5 – 8	15 – 20	6 – 12

2.3. Production

Hydrocarbon resins are produced by polymerization of the unsaturated compounds contained in the fractions described in Section 2.2 by using mainly Friedel – Crafts catalysts such as aluminum chloride and its complexes, as well as boron trifluoride and its complexes. Brønsted acids (e.g., sulfuric acid) may be also used. The term "catalyst" is scientifically incorrect with respect to cationic polymerization and should be replaced by the term initiatior – coinitiatior (initiating system) [6]. The reaction can be performed batchwise or continuously and includes the following steps:

1) Feed preparation (distillation, pretreatment, blending)
2) Polymerization
3) Deactivation of iniating system
4) Resin separation

The most important reaction parameters are feed composition, total and relative concentration of resin formers in the feed, type of catalyst and cocatalyst, catalyst concentration, and temperature. These parameters must be carefully controlled. They affect the reaction widely, in terms of yield, type (polymerization, alkylation), molecular mass, and molecular mass distribution. The particular resin feed is contacted with the initiating system by vigorous stirring. The reaction is exothermic and must be strictly temperature controlled. After reaction, the initiating system is inactivated (e.g., by addition of water, alkali, lime, or ammonia). Then the unreacted feed and the low molecular mass oligomers are removed by distillation, usually in combination with a steam-stripping process. The residual resin is conditioned in flakes, bulk, or other forms.

The proportion of catalyst in the reactant medium influences molecular mass and composition of the resin. High concentrations give resins with lower molecular mass, and lower concentrations give resins with higher molecular mass. A low concentration of catalyst may influence resin composition by selectivity (i.e., only the most reactive components are transformed). Reaction temperature affects product molecular mass, yield, and color. Molecular mass decreases and yield increases with increasing temperature.

Dicyclopentadiene resins are usually manufactured by thermal polymerization of various dicyclopentadiene feedstreams that may also contain styrene or indene.

2.4. General Properties

Depending on raw material and polymerization conditions hydrocarbon resins may range from viscous liquids to very hard solids with light to amber coloration. Special water-white types also exist. Solubility and compatibility characteristics are a function of the special resin type. All unmodified types have in common an apolar structure that gives them good water repellency and high resistance to acid, alkali, and salt solutions. They are soluble in aromatic and most common aliphatic solvents, ethers, esters, ketones, and chlorinated hydrocarbons. Unmodified resins are compatible with a wide range of other resins and polymers. The absence or presence of double bonds in the resin structure determines whether the resin is stable and/or reactive. Thus, both resins with excellent heat and weather stability and highly reactive grades are commercially available. The structure of hydrocarbon resins is very complex. The major principles involved are the following:

1) Mixtures of mono- and diolefin monomers result in paraffinic and naphthenic structures; diolefins (DCPD type) give unsaturated resins

2) Vinyl aromatic monomers (styrenes, indenes) generate chain structures with high aromatic substitution and a low degree of unsaturation
3) Bicyclic terpenes react mainly to produce cyclic structures by rearrangement

2.5. Characterization and Analysis

Hydrocarbon resins are usually characterized by their softening point, color, degree of unsaturation, saponification number, density, and ash content. These properties are determined by standardized methods (see Table 3).

Table 3. Characterization of hydrocarbon resins

Property	Method (unit)	Standard
Softening point	ring and ball RB (°C)	ASTM D 3461-76, ISO 4625
	Krämer – Sarnow KS (°C)	DIN 53 180, NFT 67 001
	Mettler	ASTM D 3461-76
Color	Gardner (50 % solution in toluene)	ASTM D 1544-80 (0-18), ISO 4630
	Barrett (8 % solution in toluene)	
	Saybolt, Hazen, APHA (for very light colors)	
Unsaturation	bromine number (g Br_2/100 g)	ASTM D 1159-84, DIN 51 774, part 1
	Wijs iodine number (g I_2/100 g)	ASTM D 1959-69
Acid number	mg KOH/g	DIN 51 558, DIN 53 402, ASTM D 974-80
Saponification number	mg KOH/g	DIN 51 559, DIN 53 401
Density	at 20 °C (g/cm^3)	DIN 51 757
Flash point	Cleveland open cup (°C)	ISO 2592

Because of their complex structure, hydrocarbon resins do not exhibit a definite melting point but soften on heating within a temperature interval. The *softening point* is defined as the temperature at which a resin, poured in a ring of defined diameter and thickness, flows under the pressure of a given weight. The most widely applied method is the ring-and-ball (RB) method; the older Krämer – Sarnow (KS) method is used more rarely. A more recent method is the Mettler method.

Color is determined optically in solution by comparison with a color standard on the Gardner scale or less commonly on the Barrett scale. For light colors the Saybolt, Hazen, or APHA method is used. A comparison of Barrett and Gardner color numbers is given in what follows:

Barrett	Gardner
B 1/2	1 – 6
B 1	7 – 10
B 11/2	11 – 12
B 2	12 – 13
B 21/2	14
B 3	15
B 4	16 – 17
B 5	18

Unsaturation is indicated by the iodine or bromine number. Neither number gives reliable information on the true degree of unsaturation, because along with addition reactions to the double bonds, substitution reactions may occur.

Other properties determining the end use of resins are solubility, compatibility, melt and solution viscosity, molecular mass, and molecular mass distribution. *Solubility and compatibility* are measured by determining the cloud point. Although generally accepted, this method is not standardized for resins. *Molecular mass and its distribution* are important resin characteristics and are determined by size exclusion (gel permeation) chromatography. Some information on resin structure is obtained by spectroscopic methods such as IR, UV, and NMR. The relation of aromatic to aliphatic protons evaluated by NMR is a useful tool for determining the aromaticity of a resin.

2.6. Resin Types

2.6.1. Aliphatic Hydrocarbon Resins

Aliphatic hydrocarbon resins are based on C_5 feedstreams and can be divided into general-purpose or basic resins, high-quality special piperylene resins, and dicyclopentadiene resins. Typical data for aliphatic petroleum resins are listed in Table 4.

Table 4. Typical data for aliphatic petroleum resins

Property	C_5 Olefin – diolefin resins	Piperylene resins
Softening point RB, °C	70 – 100	liquid – 115
Gardner color	5 – 7	3 – 7
Bromine number, g Br_2/100 g	15	25
Density at 20 °C, g/cm^3	0.93 – 0.97	0.88 – 0.97

C_5 Olefin – Diolefin Resins. Basic resins are produced from more or less narrow C_5 cuts and are available in large quantities as multipurpose resins. They have satisfactory color and color stability and a moderate degree of unsaturation. They are highly soluble in aliphatic solvents and compatible with a wide range of other resins, polymers, and waxes. Their softening point is usually between 70 and 100 °C (RB).

Piperylene resins exhibit an improved quality and are produced from highly concentrated streams that contain up to 70 % piperylene. They have properties similar to those of terpene resins because of their cycloaliphatic structure. Thus they are often called "synthetic terpene resins." They have excellent light stability and light color. A wide range of piperylene resins is produced – from viscous, liquid resins to hard resins.

Dicyclopentadiene Resins. Dicyclopentadiene resins can be divided in two main groups:

1) Those that contain predominantly dicyclopentadiene (DCPD), with high degrees of unsaturation (bromine number ca. 65 – 100 or higher) and which are distinctly heat- and oleoreactive
2) Those containing substantial amounts of aromatic structures (formed by co-reaction with unsaturated aromatics), with moderate unsaturation (bromine number ca. 55 – 57)

Because of the presence of reactive unsaturation these DCPD resins may be modified with other unsaturated components such as maleic anhydride, drying oils, or rosin (see Table 5).

Table 5. Typical data for dicyclopentadiene resins

Property	Straight DCDP resins	Aromatic-modified DCPD resins
Softening point (RB), °C	liquid – 160	10 – 150
Gardner color	6 – 11	5 – 15
Bromine number, g Br_2/100 g	95 – 100	ca. 55
Density at 20 °C, g/cm^3	ca. 1.1	1.05 – 1.12

Polybutenes, manufactured from butadiene-free C_4 fractions, are low molecular mass copolymers of the butene isomers. These polybutenes are normally low-colored, viscous liquids that are chemically stable, oxidation resistant, nondrying, and tacky (→ Polyolefins, Chap. 4.)

2.6.2. Aromatic Hydrocarbon Resins

Aromatic hydrocarbon resins are based on coal-tar-derived indene – coumarone streams or petroleum-derived C_8/C_9 streams. Typical properties of aromatic hydrocarbon resins are listed in Table 6.

Table 6. Typical properties of aromatic resins

Property	Coal/tar based	Petroleum based
Softening point RB, °C	liquid – 170	liquid – 150
Gardner color	6 – 18	5 – 12
Iodine number, g I_2/100 g	35 – 105	25 – 90
Density at 20 °C, g/cm^3	1.08 – 1015	1.06 – 1.11

Indene – Coumarone Resins [4], [5]**.** The oldest family of hydrocarbon resins is now available with an acceptably light color. Indene – coumarone (IC) resins are on the market as viscous liquids and as solids with high softening points, up to 170 °C (RB). The resins are soluble in most common solvents (except low molecular mass alcohols) and compatible with a wide range of polymeric materials. They exhibit high water repellency and resistance to acid and alkali. When not stabilized, they are subject to yellowing by autoxidation under the influence of UV light.

Petroleum Resins. The C_9 aromatic hydrocarbon resins are obtained from streams of cracked petroleum fractions that are purified to a greater or lesser extent. Depending on its origin and pretreatment, the raw material contains a varying percentage of dicyclopentadiene. The degree of unsaturation of the resin can thus be controlled by the choice of raw material. The properties of petroleum resins are generally similar to those of indene – coumarone resins, but petroleum resins are often characterized by a lower degree of unsaturation, higher light and heat stability, and a wider range of solubility and compatibility. They are produced in many different grades from viscous liquids to solids of high softening point.

Table 7. Typical data for terpene resins

Property	Derived from		
	α-Pinene	β-Pinene	*d*-Limonene
Softening point RB, °C	25 – 135	10 – 135	100 – 135
Gardner color	3 – 5	1 – 4	1 – 4
Bromine number, g Br_2/100 g	25 – 30	15 – 30	27 – 28
Density at 20 °C, g/cm^3	0.90 – 0.98	0.93 – 0.99	0.99

Table 8. Typical properties of resins from pure aromatic monomers

Property	Styrene	α-Methylstyrene	α-Methylstyrene – vinyltoluenes
Softening point RB, °C	liquid – 160	70 – 145	75 – 120
Gardner color	1 – 3	<1	<1
Bromine number, g Br_2/100 g	0	2 – 8	2
Density at 20 °C, g/cm^3	0.98 – 1.08	1.06 – 1.07	1.05

2.6.3. Terpene Resins

Terpene resins are based on naturally occurring monomers. The presence of tertiary carbon in their structure makes them very susceptible to oxidation; thus they must be protected by antioxidants.

Terpene resins are usually light colored and soluble in most common solvents. They are widely compatible with other resins and polymers, and have excellent tackifying properties. They are available as viscous liquids and in solid form. Typical properties are presented in Table 7.

2.6.4. Resins from Pure Monomers

Pure monomers such as styrenes or isobutene are excellent resin formers for the manufacture of very stable, light-colored to colorless (water-white) resins. Industrially, resins based on styrene or α-methylstyrene, or blends of mainly α-methylstyrene and vinyltoluenes, are produced. Resins from the copolymerization of terpenes and styrene are also available. Typical data of resins from pure aromatic monomers are given in Table 8.

Table 9. Typical properties of mixed resins

Property	$C_5 - C_9$ Resins	Terpene – aromatic resins
Softening point RB, °C	liquid – 105	105 – 115
Gardner color	2 – 10	2 – 5
Iodine number, g I_2/100 g	<25	not available
Density, g/cm^3	0.86 – 1.07	1.02

2.6.5. Modified Resins

In the previous sections, resins are described that are obtained from steam cracker fractions or monomer mixtures. They contain predominantly carbon and hydrogen, but no polar or functional groups. With the exception of dicyclopentadiene resins, they are chemically nonreactive. This section deals with resins that are either obtained from special, modified feedstreams or are modified after polymerization. Thus, properties of aliphatic- or aromatic-type resins may be adapted by blending initial feedstreams or by addition of selected monomers. Mixed resins of $C_5 - C_9$ types, as well as terpene – aromatic resins, are available. Typical properties are given in Table 9.

Addition of dicyclopentadiene to the initial feedstream increases the degree of unsaturation and thus the reactivity of the final resin. Also coreaction of dienes (e.g., dicyclopentadiene with maleic anhydride) may be applied. Resins made by coreaction of aromatic or terpene resin formers with phenol are well known. Their properties are listed in Table 10.

Table 10. Phenol-modified resins

Property	Based on	
	C_9 and indene – coumarone	Terpene
Softening point RB, °C	liquid – 120	95 – 155
Gardner color	5 – 8	4 – 11
Hydroxyl number, mg OH/g	56 – 112	80 – 260
Density at 20 °C, g/cm^3	1.08 – 1.1	1.03 – 1.09

Table 11. Typical properties of hydrogenated resins

Property	Based on			
	DCPD	C_9 Fraction	Aromatic monomer	Terpene
Softening point (RB), °C	85 – 140	70 – 140	liquid – 125	85 – 115
Gardner color	< 1	> 1	crystal clear	< 1
Bromine number, g Br_2/100 g	2 – 3	not available	not available	10 – 20
Density at 20 °C, g/cm^3	1.10	0.98 – 0.99	0.92 – 1.04	0.94 – 1.01

The high reactivity of terpenes makes them suitable for copolymerization reactions with other monomers, e.g., styrenes or maleic anhydride.

Resins may also be modified by further reaction of the final resin; for example, dicyclopentadiene resins can react with maleic anhydride, unsaturated fatty acids, or rosin upon heat treatment. A very important modification is the catalytic hydrogenation of resins, which gives high-quality water-white resins with a different solubility and compatibility profile than the original resin. Dicyclopentadiene resins are hydrogenated in large quantities. Hydrogenated aromatic resins derived from steam cracker streams or pure monomers and hydrogenated terpene resins are also available. Typical properties are listed in Table 11.

2.7. Uses

Hydrocarbon resins are used in numerous fields of application because of their versatile properties. They are seldom used alone but mainly in conjunction with other materials to adapt their properties to special requirements. Hydrocarbon resins are mostly used as tackifiers, binders, processing aids, film formers, reinforcing agents, and extenders.

With regard to their specific properties, the following classification is often used:

- Hard resins (binders, film-formers) in the paint, varnish, printing and coatings industries
- Tackifiers in the adhesives, sealants, and rubber industry
- Processing aids (plasticizers) in the plastics industry (rubber goods, tires, PVC)
- Fixing agents, e.g., in wood protection
- Water repellents in various applications (e.g., wood protection, coatings)

The most important applications are in adhesives (construction, solvent- or water-based, hot-melt and pressure-sensitive adhesives), coatings (paints, varnishes, roadmaking), the rubber and plastics industry (mainly mechanical rubber goods and tires, also PVC), printing inks, and, to a lesser extent, in various other industrial fields. A generalized view of the main application areas by resin type is given in Table 12. The large group of modified resins is used in applications where special properties are required.

Table 12. Main application areas by resin type

Resin type	Adhesives	Coatings	Paints	Printing inks	Rubber
Aliphatic C_5 *	x	x	x		x
Aromatic C_9 **	x	x	x	x	x
Mixed aliphatic/aromatic	x	x	x		x
Dicyclo-pentadiene		x	x	x	x
Modified DCPD				x	
Butene	x	x			
Pure monomer	x	x	x		
Hydrogenated	x	x			
Terpene	x				

* Petroleum resins; ** Petroleum and indene – coumarone resins.

Aliphatic resins are used extensively in hot-melt adhesives; in pressure-sensitive adhesives based on natural or thermoplastic rubber; in coatings, road-marking formulations, mastics, caulks, and sealants; and in rubber formulations for mechanical goods and tires. *Aromatic C_9* and *indene – coumarone* resins are widely applied in hot-melt formulations based on ethylene – vinyl acetate or thermoplastic rubber; in solvent-based and waterborne adhesive formulations; in the rubber industry (tires and mechanical goods); and in paints, varnishes, coatings, printing inks, sealants, wood protection, and concrete curing. *Terpene resins* are used almost exclusively in

the adhesive industry as excellent tackifiers for pressure-sensitive adhesives and hot-melt formulations. *Dicyclopentadiene resins* are generally applied in paints, varnishes, and coatings where they are introduced in the binder system, and in the printing ink industry. *Water-white resins* are used in adhesives and coating formulations where light color and color stability are important. The liquid polybutylenes are used in sealants, caulks, mastics, and pressure-sensitive formulations. The large group of modified resins is used in applications where special properties are required.

Adhesives [7]**.** Most synthetic adhesives are based on a "backbone" polymer, tackifying resins, and a carrier (solvent, water, or heat) that gives the formulation the necessary consistency for application. Tackifying resins regulate the final rheological properties of the system (tack, specific adhesion, and wetting).

Solvent-borne adhesives, mainly based on SBR and polychloroprene rubber, are frequently combined with hydrocarbon resins (aromatic C_9 and indene – coumarone , aliphatic and mixed C_5/C_9), as well as rosin, rosin esters, terpene – phenolic, and *p-tert*-butylphenolic resins.

Waterborne adhesives are increasingly being used for environmental reasons. Polymer dispersions based on poly(vinyl acetates), latexes, or acrylates may be modified by addition of tackifying resins such as petroleum and indene – coumarone resins, terpene resins, as well as rosin esters, terpene – phenolic resins, and ketone resins.

Hot-melt adhesives are thermoplastic solids which are liquified by heating for application. Backbone polymers for these adhesives are ethylene – vinyl acetate (EVA), thermoplastic rubbers, such as styrene – isoprene – styrene block copolymers, polyethylene, and polypropylene, formulated together with tackifying resins. Polyesters and polyamides, which are also used in hot-melt adhesives, do not need additional tackification. Hot-melt adhesives formulated with the above-mentioned polymers contain paraffins or waxes, tackifying resins, and fillers. Tackifying resins of various types may be used, mainly hydrocarbon resins (aliphatic C_5, aromatic C_9, indene – coumarone, mixed aliphatic – aromatic, terpene and hydrogenated resins), rosin and rosin esters, and terpene – phenolic resins.

Pressure-sensitive adhesives are defined as adhesives which in solvent-free form remain permanently tacky and adhere instantaneously with application of a minimum of pressure. Their main use is in tape and label manufacturing. Formulations are based on backbone polymers such as rubbers (natural rubber, SBR), and block copolymers, together with tackifying resins, or on acrylic resins. Tackifying resins for this use are aliphatic C_5, aromatic C_9, mixed C_5/C_9, pure monomer, terpene, and hydrogenated resins, as well as rosin and rosin esters.

Sealants. Sealants are based on polymers such as butyl rubber, polyisobutene, thermoplastic elastomers, SBR, neoprene, and polysulfides. Addition of tackifying resins is necessary to improve instantaneous adhesion. Practically all hydrocarbon resin types as well as rosin and modified rosin are usable. Other basic raw materials for sealants, such as silicones or urethanes, do not need additional tackification.

Coatings. Coatings [5], [8] range from protective to decorative and can be intended for temporary or permanent use. Hydrocarbon resins are extensively used, as illustrated by the following examples:

- Hot-melt coatings are mainly used in the packaging industry. Formulations and tackifiers used are very similar to those for hot-melt adhesives.
- Paints and varnishes, based on a variety of binder systems, may use rosin derivatives as well as hydrocarbon resins of the aromatic, aliphatic, and DCPD type as hard resins. Aromatic hydrocarbon resins are especially important in the formulation of aluminum paints.
- Road-marking material of the paint or hot-melt type uses mainly aliphatic C_5 resins but also C_9 types, modified by straight or cyclic aliphatics, as well as hydrogenated and special C_9 resins.
- Anticorrosion paints may be based on C_5, C_9 and DCPD resins, mixed C_5/C_9 resins, and phenol-modified aromatic resins.
- Concrete curing membranes, applied to concrete to avoid too rapid drying, contain hy-

drocarbon resins (DCPD, C_5 and C_9) in solution or dispersion.
– Wood protection by impregnation or surface treatment is carried out with, e.g., solutions containing aromatic C_9 resins because of their excellent water-repellent and fixing properties.

Printing Inks. Use of hydrocarbon resins in ink formulation takes advantage of their good compatibility with many ink components, e.g., alkyds, oils, and ink solvents, and gives the ink gloss and good resistance to water and alkali. Hydrocarbon resins are usually formulated together with the classical ink binders such as alkyd resins and modified rosins. High-softening-point hydrocarbon resins of the aromatic C_9 and indene – coumarone type, unmodified and modified, as well as DCPD and functional modified DCPD resins are used. The main use is in offset and gravure inks.

Tires and Mechanical Rubber Goods. Rubber stocks are compounded with a multitude of different additives: processing aids, plasticizers, reinforcing agents, tackifiers, pigments, antioxidants, and curing agents. Resins widely used in this application are generally referred to as processing aids, but in fact they have multiple functions. They promote processing by lowering viscosity, improve the building tack of unvulcanized mixtures, and may improve elongation, tensile strength and flex resistance of the vulcanized materials. Besides alkyl-phenolic resins, the largest volume resins for this application, considerable quantities of hydrocarbon resins, aromatic C_9 and indene – coumarone resins, C_5 aliphatic, mixed aromatic/aliphatic, and DCPD resins, as well as some unmodified rosin are used. The main criteria for choice are availability, consistency, and price.

Other Uses. Hydrocarbon resins are used in many other applications, such as in compounding floor tiles, in the foundry industry as binder and lustrous carbon former, as oil additives, in investment casting, the ceramic industry, in textile treatment and waterproofing, as well as in gypsum waterproofing.

2.8. Economic Aspects [9]

The total capacity for synthetic hydrocarbon resin production is estimated to be about 1×10^6 t/a worldwide in 1991. Main capacities are located in the United States, Canada, and Brazil (ca. 0.45×10^6 t/a); Europe (roughly 0.25×10^6 t/a); and the Asia/Pacific region (about 0.3×10^6 t/a).

Aromatic resins represent a volume of ca. 44 %, C_5 and DCPD resins ca. 37 %, and hydrogenated resins ca. 19 %. Producers and trade names of hydrocarbon resins are listed in Table 13.

3. Resins by Condensation

3.1. Furan Resins

The term "furan resins" describes generic polymers or resins that are derived from the condensation of furfural and/or furfuryl alcohol alone, and with a variety of coreactants. These include formaldehyde or a formaldehyde precursor such as paraformaldehyde, urea – formaldehyde concentrates or syrups, phenol, phenol – formaldehyde resins, aldehydes, ketones, and polyhydroxyl-substituted aromatics. Polymers or resins derived from 2,5-bis(hydroxymethyl)furan (BHMF) have been reported. With 2,5-BHMF, both condensation and addition polymers can be synthesized.

3.1.1. Monomers

Although many chemicals possess a furan nucleus in their molecular structure, furfural and furfuryl alcohol are the only monomers of major industrial significance. *Furfural* [*98-01-1*] is produced commercially from agricultural byproducts such as corncobs, sugarcane bagasse, oat hulls, and wood residues [10] (→ Furan and Derivatives, Chap. 3.). *Furfuryl alcohol* [*98-00-0*] is produced by hydrogenating furfural in a vapor- or liquid-phase process with a variety of catalysts based primarily on copper [11]. *2,5-Bis(hydroxymethyl)furan* [*1883-75-6*] is synthesized by selective hydroxymethylation of furfuryl alcohol [12] or by hydrogenation of the less readily available 5-hydroxymethylfurfural [13].

Table 13. Resin manufacturers and trade names

	Trade names	Resin types
Europe		
Akzo (Netherlands)	Setalin	hydrocarbon-modified phenolic resins
Cray Valley (France)	Norsolene	C_9 and C_5-C_9 resins
DRT (France)	Dercolyte, Dertophene	terpene and modified terpene resins
DSM (Netherlands)	Uratak	C_9 and phenol-modified C_9 resins
Enichem (Italy)	on stream in 1994	C_5 resins

3.1.2. Production – Characteristics

Furfural and furfuryl alcohol are converted to resins by *condensation polymerization*.

Furfural-Based Resins. Homopolymerization of furfural, although studied extensively [14], has no industrial importance. Copolymers of furfural with phenol, phenol – formaldehyde resins, and other hydroxyl-substituted aromatics have been available commercially for many years. Since the acid- catalyzed reaction of furfural and phenol is difficult to control, most industrial processes involve the use of alkaline catalysts such as alkali hydroxides or carbonates. Furfural and ketones (usually acetone) condense with alkaline catalysts to form furfurylidene acetone monomer, which polymerizes to a thermoset resin in the presence of strong acid.

Furfuryl Alcohol-Based Resins. The mechanism proposed up to the early 1950s for the polymerization of furfuryl alcohol was reported by Dunlop and Peters in their treatise on furans [10]. As a result of the growing importance of furfuryl alcohol resins since the 1950s, the chemistry of furfuryl alcohol polymerization initiated by heat, acid, and alumina has been studied extensively and has proved to be complex. Studies dealing with the identification of intermediates and byproducts by spectroscopic and chromatographic techniques [15–18], the reaction kinetics involved in polymerization [19–21], the structure of the resulting polymers [22], and the nature of the oxygen- or acid- catalyzed cross-linking of the initial resin have all led to a better understanding of this complex chemistry [23]. A comprehensive review examines the literature up to 1977 and interprets the resinification mechanisms [14]. A more recent review further clarifies the two-stage polymerization of furfuryl alcohol [12]. Based on accumulated data, furfuryl alcohol must be considered a bifunctional monomer in the initial stages of weak acid catalysis, and its "normal" reactions give linear chains or oligomers containing essentially two repeating units (**1**, **2**), with **2** predominating:

1

2

The polymerization or resinification of furfuryl alcohol is highly exothermic and, depending on the activity and concentration of the catalyst used, requires careful control of reaction temperature. Generally, weak acids such as carboxylic acids or metallic salts are used to produce oligomeric prepolymers with repeating moieties **1** or **2**. Further conversion of these prepolymers to cross-linked thermoset resins is accomplished by the addition of strong inorganic or organic acids. Aromatic sulfonic acids are the preferred catalyst. Earlier investigators postulated cross-linking through the C-3 and C-4 positions of the furan ring. However, more recent studies [24], suggested, on the basis of analytical data, that the main cause of branching and cross-linking is a condensation reaction between methylene groups within a chain and a hydroxymethyl group at the end of another chain to yield structures such as **3**.

3

2,5-Bis(hydroxymethyl)furan. The 2,5-BHMF monomer behaves as a diol and undergoes esterification (base-catalyzed transesterification), alkoxylation, glycidyl ether formation, cyanoethylation, and urethane formation. In the presence of an acid catalyst, resinification of 2,5-BHMF occurs, similar to that of furfuryl alcohol, although the end groups of the resulting resin are hydroxymethyl. These resins are characterized by enhanced reactivity compared to acid-catalyzed furfuryl alcohol resins [25]. 2,5-Bis(hydromethyl)furan resins convert to highly cross-linked thermosetting polymers that demonstrate unique characteristics in composites, including a desirable high char yield on carbonization, low flame propagation, corrosion resistance, and superior high-temperature stability.

3.1.3. Uses

Furan resins are used in a variety of applications including sand cores and molds for metal casting; corrosion-resistant fiberglass-reinforced plastics; low flammability and low smoke generating composites and foams; carbonaceous products; polymer concretes; wood adhesives; and proppants in oil-well sand consolidation.

The use of *furfuryl alcohol resins* in the worldwide foundry industry remains the only important application. Total world production of furan resins for use as binders to produce sand cores and molds for metal castings exceeds 75 000 t/a.

3.2. Ketone and Aldehyde Resins

Ketone and aldehyde resins are obtained from aliphatic aldehydes and aliphatic or aliphatic–aromatic ketones by self-condensation, or more frequently by cocondensation with formaldehyde [26], [27]. Other monomers such as phenols or urea are also sometimes incorporated. Although these resins have been known for a long time, new types of resin and new areas of application are always being found. In paints and coatings, as in many other areas, these resins are used in combination with other binding agents, plasticizers, pigments, and process materials [28–40].

They are also used in printer and copier technology [41–43], the production of printed circuit boards [44], adhesives [45–48], binding agents for corrugated cardboard [49–51], molding sands [52], [53], and laminates [54–56]. The production of aqueous dispersions has also been described [57].

Reaction Mechanism. The condensation of aliphatic or aliphatic–aromatic ketones with formaldehyde is base catalyzed [58]. Formaldehyde adds first to the ketone, with formation of the aldol:

The aldol is then either dehydrated to give vinyl ketones, which can polymerize or reacted with excess formaldehyde to form highly reactive methylol compounds. The reaction pathway followed depends on the molar ratio of ketone to formaldehyde and on reaction conditions (pH, temperature, concentration).

The resins are formed by polymerization of the vinyl ketones to give polymers with an alternating structure (see Fig. 1) or by complex condensation of the methylol compounds with one

another or with other ketone molecules to give partially branched products. In industrial processes, both mechanisms often operate in parallel. An excess of formaldehyde can lead to reduction of carbonyl groups to hydroxyl groups [59]. The tendency of the vinyl ketone intermediate to polymerize is rather independent of the nature of the ketone used [60], [61], provided the vinyl group is not substituted.

Figure 1. Resins from acetophenone and formaldehyde R = Phenyl. R^2 = Aliphatic hydrocarbon.

3.2.1. Resins from Aliphatic – Aromatic Ketones

Industrially mainly acetophenone is reacted with formaldehyde. Derivatives of acetophenone with alkylated benzene rings, such as methyl-, ethyl-, *tert*-butyl-, or cyclohexylacetophenone can also be employed [62]. Besides the unmodified resins, their hydrogenation products and the resins derived from them are available commercially (see Fig. 1).

3.2.1.1. Acetophenone – Formaldehyde Resins

Acetophenone – formaldehyde resins are light-colored nonhydrolyzable products, with sufficient lightfastness and softening points of 75 – 85 °C. They are readily soluble in aromatic hydrocarbons, esters, ketones, and glycol ethers, but insoluble in alcohols, aliphatic hydrocarbons, and mineral oils. Other physical and technical properties are listed in Table 14. The resins are compatible with nitrocellulose; copolymers of vinyl chloride; chlorinated rubber; maleic, urea, melamine, and ketone resins; plasticizers; and a few alkyd resins. They are incompatible with the majority of alkyd resins, drying oils, polyesters, and polyacrylates. Their relatively low price, gloss-improving properties, and capacity to increase the solid material content of coatings (i.e., the coating can be laden with a higher solids content and the viscosity remains constant when ketone resins are added) should be mentioned in particular.

Production. *Light, soluble, hard resins* are obtained by heating an aqueous mixture of acetophenone, formaldehyde, and potassium or sodium hydroxide to the boiling point. Solvents such as alcohols can also be used. Strong acids, such as sulfuric acid, or dehydrating salts, such as zinc chloride, are also suitable condensing agents but are less common. Quaternary nitrogen or phosphorus bases [63] are used as condensing agent to obtain particularly high-melting resins. Under suitable conditions, sodium sulfite leads to low molecular mass, water-soluble condensates [64]. Formaldehyde is added mostly as a 30 % aqueous solution or as paraformaldehyde.

Larger quantities of alkali hydroxide and higher temperature result in resins that are infusible and not readily soluble, because the methylol intermediates cross-link with one another. Readily soluble, fusible condensates are obtained with ca. 0.2 mol of hydroxide per mole ketone and a sufficiently short reaction time, so that the molecular mass cannot rise above 400 – 800. Generally, increasing the reaction temperature and time results in a higher softening point, while the solubility and compatibility deteriorate. This is probably due to competing reaction mechanisms during condensation. If conditions are such that vinyl phenyl

ketone is produced mainly as the intermediate, resins with low softening point and solubility in a broad range of solvents are formed. For example, reaction of 1 mol of acetophenone with 0.05 – 0.5 mol of formaldehyde gives an oil-compatible resin. If methylol intermediates are predominantly formed, the resins have higher melting points and are limited in their solubility and compatibility. Resins with these properties are obtained from acetophenone and formaldehyde in the ratio 1: 1.

Uses. Acetophenone – formaldehyde resins are used as favorably priced binding agents in coatings and printing inks, in combination with other coating raw materials such as nitrocellulose. They improve gloss, intensity, covering capacity, solid material content, adhesion, and drying. In nitrocellulose lacquers the ease of pigmenting and polishing on wood is increased. Acetophenone – formaldehyde resins are also used in vinyl chloride copolymer coatings for metal coating and road-marking paints. Adhesives and hot melts are also formulated with these resins.

Trade Name. Synthetic Resin AP (Hüls).

3.2.1.2. Modified Acetophenone Resins

Hydrogenation of acetophenone – formaldehyde resins, in particular, gives products that differ markedly from the usual ketone and aldehyde resins and therefore open up new areas of application. The reaction of hydroxyl groups, which are formed from the keto groups on hydrogenation, with aliphatic diisocyanates gives high-quality special binding agents (see Fig. 1 and Table 14).

Properties. The hydrogenated resins are very light- colored and particularly stable. They are completely free of formaldehyde, which can no longer be formed by retroaldol-type reactions. Depending on hydrogenation conditions, resins are obtained in which only the keto groups are converted into hydroxyl groups or in which the aromatic ring is also hydrogenated [65]. Only the former are available on the market. Their softening points lie in the range 110 – 120 °C and they are readily soluble in alcohols. The resins can be diluted with aromatics but are insoluble in aliphatics and mineral oil. Their compatibility with alkyd resins is better than that of nonhydrogenated products.

The hydroxyl values of these resins are > 300 mg KOH/g. The OH groups can be reacted with diisocyanates to give extremely high-melting resins (*mp* ca. 160 °C), which are also alcohol soluble. Diisocyanate-modified resins are even more stable and exhibit rapid solvent release.

Production. Under mild hydrogenation conditions only the keto groups are hydrogenated (Fig. 1). The reaction is controlled by determination of the oxygen content and the melting point [66]. Hydrogenation can be carried out catalytically in solution or in the melt [67], [68]. Reactions with diisocyanate take place at slightly elevated temperature with the usual catalysts.

Uses. Modified acetophenone – formaldehyde resins are high melting and stable. They are therefore used as hard resin components together with other binding agents in paints and coatings, printing inks, and adhesives, if high-quality coatings are required. The *hydrogenated resins* are used for lightfast nitrocellulose-based overprinting inks for paper. They are also used in ballpoint pen pastes, inks, and toners; as flow-control agents for powder coatings; as hard resin components in isocyanate reactive systems; and for modification of alkyd resins.

The *isocyanate-modified resins* are used in high-quality printing inks, in paper and wood varnishes, and in the formulation of coatings with good adhesion to plastic surfaces. They are particularly suitable for wetting and stabilizing aluminum pigments in paints and printing inks.

Trade Names. Synthetic Resin SK (hydrogenated resin) and Synthetic Resin 1201 (diisocyanate-modified, Hüls).

3.2.2. Resins from Aliphatic Ketones

Resins are produced from linear aliphatic ketones – principally methyl ethyl ketone and acetone – and formaldehyde. Methyl isobutyl ketone is also used, mainly for the production of adhesives [69], [70]. Cyclohexanone and

methylcyclohexanone are most important in the synthesis of alicyclic resins, although reactions of cyclopentanone, cycloheptanone, and cyclic ketones with longer side chains have also been described [71].

3.2.2.1. Methyl Ethyl Ketone – Formaldehyde Resins

Methyl ethyl ketone is still important for the production of binding agents for paints, coatings, and adhesives. These resins differ from alicyclic and aromatic ketone-based products in certain application-relevant properties, such as solubility in various solvents and compatibility with other lacquer raw materials. These properties may be explained by the high polarity of the ketone and its special behavior in the alkali-catalyzed condensation with formaldehyde [59].

Physical Properties. Methyl ethyl ketone – formaldehyde resins are lightly colored and are soluble in polar organic solvents such as alcohols, esters, ketones, and glycol ethers. The hydroxyl values are in the range 80 – 190 mg KOH/g. The strongly polar resins have a total oxygen content of 21 – 29 wt % and are hygroscopic. Depending on production conditions, the molecular mass lies between 3000 and 5000, and the melting range between 80 and 120 °C. Other physical data and compatibilities are described in [27].

Chemical Properties. Methyl ethyl ketone – formaldehyde resins are unhydrolyzable. The keto and hydroxyl groups and the carbon double bonds give the compounds a certain degree of chemical reactivity. Hydrogenation leads to clear, colorless resins [72]. The hydroxyl groups can be esterified with carboxylic acids or acid anhydrides [73] and can react with isocyanates [74].

Production. Industrially, ketone resins are obtained by alkali-catalyzed condensation of methyl ethyl ketone and formaldehyde (molar ratio 1: 2 – 1: 2.5). Condensation is performed mainly batchwise [59], [75], [76]. Continuous production has also been described [77]. The unpurified ketone is treated with formaldehyde in the presence of water and sodium or potassium hydroxide as catalyst. By increasing the formaldehyde content, the melting range can be raised to 80 – 120 °C.

Special purification processes give light, high-melting products [78]. High softening points are also achieved by using phase-transfer catalysts [72]. The reaction mechanism is not completely understood and involves many concurrent reactions [27].

Uses. Methyl ethyl ketone – formaldehyde resins are used in combination with film-forming agents such as nitrocellulose, acetylcellulose, cellulose ethers, and natural resins. They impart hardness, drying, polishing ability, and good lightfastness. The capability to gelatinize nitrocellulose is exploited in the production of high-gloss nitro lacquers. The free hydroxyl groups are used for cross-linking in isocyanate-reactive coatings, adhesives [79], and molding sands [74].

3.2.2.2. Acetone – Formaldehyde Resins

The alkali-catalyzed condensation of acetone and formaldehyde does not lead to useful, solid synthetic resins. The considerably greater hardening tendency of the unstable methylol intermediates from acetone in comparison to those of other carbonyl compounds [80], [81] leads to a cross-linked, insoluble final product. *Self-hardening precondensates* can, however, be produced, which are used alone or in combination with other hardenable precondensates, such as phenol resols.

Uses. Hard foams [82] are obtained by foaming the methylol compounds in the presence of alkali hydroxide alone or of alkali hydroxide and an elastomer latex [83]. Sands can be hardened with acetone – formaldehyde precondensates for the production of moldings [84–86]. Rapidly hardening moldings made from cement have also been described [87], [88]. Acetone – formaldehyde condensates are used widely in paper [89] and wood adhesives [90]. Phenol resols are often cocondensed to obtain particularly weather-resistant wood materials and chipboard [91–93] or for the waterresistant adhesion of corrugated paperboard [94]. Other uses of acetone

precondensates are in photoreceptors in electrophotography [95], [96] and in production of thickeners and emulsifiers [97], [98].

3.2.2.3. Cyclohexanone Resins

Cyclohexanone and methylcyclohexanone readily undergo self-condensation, in addition to mixed condensation with formaldehyde [99]. The former involves aldol condensation between the carbonyl group of one molecule and the activated methylene group of another. The carbonyl group of the intermediate then reacts with another cyclohexanone molecule, etc. The reaction occurs at elevated temperature and can be catalyzed by basic, acidic, or neutral agents.

Properties. The softening points of the light, neutral resins are between 80 and 120 °C. Under normal conditions the resins are resistant to acids and bases. However, they eliminate water in the presence of acids at elevated temperature (> 80 °C), thus altering their properties significantly. Cyclohexanone resins are lightfast, soluble in many solvents, and compatible with most coating raw materials (see Table 14). They are more expensive than cyclohexanone – formaldehyde resins [99]. An example of the production process (according to [100], [101]) is given in [27].

Uses. Cyclohexanone resins are used in coatings, mainly to improve intensity, gloss, and hardness. They can also improve light and weather resistance, as well as adhesion. In quantities of 5 – 50 % (based on the film-forming agent) these resins are added to coatings based on alkyd resins, vinyl chloride copolymers, chlorinated rubber, nitrocellulose, or oils. Their use as carrier resins for pigment preparations has also been described [102].

Trade Name. Laropal K 80 (BASF).

3.2.2.4. Cyclohexanone – Formaldehyde Resins

Cyclohexanone can react with aldehydes, in particular formaldehyde, to give defined methylol compounds or resinous products. The molar ratio and the reaction conditions determine the final products. A large formaldehyde excess promotes the formation of methylol compounds, whereas basic catalysis leads to resin formation [103], [104]. Higher aldehydes can also be used instead of formaldehyde, but they have not gained any industrial importance. In addition to cyclohexanone, methylcyclohexanone or mixtures of cyclohexanone with aliphatic ketones are also used as the component with the activated methylene group [105]. The resins can be modified with phenols [100], [106], epoxides [107], polyesters [108], and sulfonamides [109]. Gritty products are obtained by the addition of dispersion agents [110]. Continuous production has been described in [111] and [112]. The lightfastness can be increased by hydrogenation [113] and treatment with reducing agents [114].

Properties. Cyclohexanone – formaldehyde resins do not exhibit the broad compatibility and solubility of cyclohexanone resins. However, they are cheaper and nevertheless sufficiently lightfast. They can be combined with a range of binders for coatings, but not with oils (see Table 14). The use of methylcyclohexanone as a raw material generally leads to better solubility and compatibility.

Production. Industrially, cyclohexanone is condensed with formaldehyde in the presence of alkali. An example of the production procedure is given in [27], where the modification with phenol is also described.

Uses. In many cases, cyclohexanone – formaldehyde resins are used to improve drying, hardness, intensity, gloss, and solid material content. In paints and coatings they are always used as additives in addition to other binding agents, for example, in alkyd – acrylate varnishes [115], cement paints [116], epoxy resin systems [117], and marine paints [118]. In addition to their use in conventional printing inks [119], [120], they are increasingly being used in UV-hardening printing inks [121–123]. Another important area of application is in adhesives [124–126] and sealants [127]. The use of these resins in optical recording media has also been described [128], [129].

Trade Names. Synthetic Resin AFS (Bayer), Synthetic Resin CA (Hüls), L2 Resin (Leuna), Krumbhaar type resins (Lawter).

3.2.3. Aldehyde Resins

In the 1970s, aldehyde resins synthesized from isobutyraldehyde, formaldehyde, and urea were developed to an industrial level. α-Ureidoalkylation formed the basis of the synthesis and is described in detail in [130]. Aldehyde resins from isobutyraldehyde and phenol are used in melt adhesives [131], [132].

Isobutyraldehyde – Formaldehyde – Urea Resins. Both the reaction of urea with enolizable aldehydes [133] and the reaction of urea, formaldehyde, and enolizable aldehydes [134] in an acidic medium lead, on subsequent treatment with alkali alkoxides, to resinous products. The process can be described as follows (see above).

Properties. The isobutyraldehyde – formaldehyde – urea resins are slightly colored and fairly lightfast. Their melting points lie in the range 80 – 110 °C. The solubility and compatibility with other coating binders can be varied, depending on the production process. Thus products soluble in aliphatics and all other common solvents are on the market. Their compatibility is, however, limited to acrylate resins and some cellulose derivatives (see Table 14). The available functional groups can be seen in the above formula scheme.

Production [134]. Formaldehyde, isobutyraldehyde, and urea are reacted in the presence of sulfuric acid. The condensation is carried out for 3 h at 80 °C. After the addition of xylene the mixture is stirred for another 20 min at 75 °C, and the aqueous phase is separated. The organic phase is treated first with sodium methoxide and then neutralized with 75 % sulfuric acid. The resin resulting after work-up has a pale-yellow color and a softening point of 80 – 82 °C.

Uses. Like ketone resins, aldehyde resins can be added to other coating binders. Improvements in hardness, gloss, intensity, flow, resistance to yellowing, and solid material content are achieved in coatings based on alkyd resins, nitrocellulose, or chlorinated polymers. By the addition of aldehyde resins, the overall formulation can often be made more economical (e.g., in powder coatings, where the flow is improved at the same time). Another area of use is in hot meltings and spray plastics for road markings. Some aldehyde resins are suitable as mixing resins for pigment pastes with broad solubility and compatibility. A high pigment-binding capacity and low solution viscosity have thus far not been achieved with ketone resins. For aqueous dispersions see [135].

Trade Names. Laropal A types (BASF).

3.3. Polyamide Resins

Polyamides are thermoplastic polymers with repeating amide units (−CO−NH−) in the main chain (→ Polyamides).

Polyamide resins (PA resins) also belong to the polyamide group. However, PA resins are based on dimerized fatty acids, and their molecular mass is generally less than 15 000; thus they differ considerably from high molecular mass polyamides in their chemical structure and

properties [136]. Whereas high molecular mass polyamides are important synthetic fibers and engineering plastics, polyamide resins are used as hotmelt adhesives, casting compounds, and binders for printing inks.

3.3.1. Physical and Chemical Properties

The physical and chemical properties of PA resins can be varied within wide limits through the choice and ratio of raw materials used. Brittle, tough-hard, or flexible PA resins can be produced, which have very different tensile strengths and elongation values [137].

The density of PA resins is ca. 0.95 g/cm^3. The *softening point* is in the range of 80 – 250 °C, preferably between 90 and 190 °C. Melt viscosities are between 0.1 and 100 Pa · s at 220 °C. The water absorption of PA resins is between 0.5 and 3 % after 28-d storage in water and is thus much lower than the water absorption of industrially relevant polyamides. All PA resins show good resistance to chemicals. They are generally resistant to water, dilute alkali, weak acid, oils, and fats. Most PA resins are moderately stable to unstable toward esters, ketones, alcohols, and aliphatic hydrocarbons. Some are resistant to chlorinated hydrocarbons.

3.3.2. Raw Materials

The dimerized fatty acids required for the production of PA resins are obtained by heating mono- or polyunsaturated fatty acids, such as oleic, linoleic, or linolenic acids or their esters with or without a catalyst. The dimerized fatty acids formed have an open- chained, cyclic-unsaturated, or aromatic structure [138].

In addition to dimerized fatty acids, dicarboxylic acids are frequently used as comonomer. Examples are adipic acid, azelaic acid, sebacic acid, decamethylenedicarboxylic acid, terephthalic acid or its ester, or isophthalic acid. Ethylenediamine, hexamethylenediamine, 1,12-diamino-4,9-dioxadodecane, piperazine, dipiperidylpropane, and polyoxypropylenediamine are used as the polyamine component [139]. 6-Aminocaproic acid in the form of its lactam and 11-aminoundecanoic acid are the preferred aminocarboxylic acids.

3.3.3. Production

Polycondensation of the aforementioned monomers is carried out in a reactor equipped with a stirrer and condenser at 150 to 250 °C with exclusion of air (Fig. 2). The reaction is performed initially under normal pressure and then under reduced pressure. The water formed in the reaction is distilled off. When the condensation reaction has gone to completion the product is removed as a melt, cooled, and ground or poured into special molds.

3.3.4. Quality and Analysis

For quality testing and characterization of the products the following procedures are used:

The *softening range* is measured by the ring-and-ball method (DIN 52 011 or ASTM E-28). Melting points determined by differential scanning calorimetry or thermomechanical analysis, or microscopic melting points are sometimes given.

Melt viscosities are measured with rotation viscometers. The values obtained can vary considerably, depending on the type of viscometer used. For highly viscous products the *melt index*according to DIN 53 735 or ASTM D-1238 is sometimes determined. The *tensile strength* and *elongation* are determined according to DIN 53 455 or ASTM D-1708. The *water absorption* is determined according to DIN 53 495 or ASTM D-570. The *acid value* is determined according to DIN 53 402 and the *amine value* according to DIN 16 945.

3.3.5. Storage

Polyamide resins are usually supplied as pellets. Because many machines for further processing can only handle rods, cylinders, or rectangular blocks, PA resins are also supplied in these forms.

Since problems can arise in processing if the product is damp, moisture-proof packaging is recommended. With proper storage, the shelf-life of PA resins is virtually unlimited.

Figure 2. Polyamide resin production
a) Reaction vessel; b) Condenser; c) Separator; d) Filter; e) Cooling band; f) Granulator

3.3.6. Uses

Thermoplastic PA resins are used as high-performance hotmelt adhesives [140], casting compounds [141], binders for printing inks, overprinting lacquers [142], and thixotropic agents for alkyd resin coatings [143].

In the shoe industry, PA hotmelt adhesives have been used for many years as an aid in assembly for bonding the upper leather to the insole (lasting). The furniture industry utilizes PA hotmelt adhesives for heat-resistant edge banding of chip or particle board.

In the automobile industry, PA hotmelt adhesives are used for interior trim. The bonding of air and oil filters by using PA hotmelt adhesives is particularly important. A relatively new area of application is the sealing of wires and cables into car- connectors by potting with PA resins. Connectors are being incorporated more frequently in the car because of the increased use of electronic control systems. In the electrical and electronics industries, PA resins are used because of their relatively high heat resistance and good insulating properties. In addition to bonding radio and television housings and loudspeakers, in particular coil winding, coil ends, and other electronic components are fixed and bonded with PA hotmelt adhesives.

In the telecommunications sector, PA hotmelt adhesives are used to bond and seal cables and heat-shrink components, and to protect telephone cables from moisture and corrosion at the ends or connection points. In the textile industry, PA resins are used for "cleaning-resistant" bonding of interlining to textiles [144].

PA resins are also used as binders for printing inks. Printing inks based on PA resins are particularly suitable for printing on nonporous materials, such as plastic films, because of their good adhesion, flexibility, and gloss. Since the printed films show good resistance to chemicals and abrasion, they are also used as overprint lacquers.

In the area of transparent lacquers, which are applied by gravure or flexographic printing, PA resins are used as cold-seal release lacquers, antislip varnishes, or heat-seal varnishes.

3.3.7. Producers, Trade Names

The PA resins are sold under the following trade names: Euremelt, Eurelon (Schering, Germany); Versamid, Macromelt (Henkel, Germany); Reamide (Chemplast, Italy); Unirez (Union Camp, United States); Versamid, Versalon (Cray Valley Products, United Kingdom); Polymid (Lawter, United States); Evacor (Evode, United Kingdom); Sunkem (Sun Chemical, United States); Terlan (Lambiotte, France); Casamid (Swan, United Kingdom); Emerez

(Emery, United States); Sunmide (Sanwa, Japan); Polymide (Sanyo, Japan).

4. Natural and Synthetic Resins – Toxicology and Legislation

4.1. Toxicology

4.1.1. Rosins and Their Derivatives

For review, see [145].

Crude Rosins (→ Resins, Natural, Chap. 5.2., → Resins, Natural, Chap. 5.3., → Resins, Natural, Chap. 5.4., → Tall Oil). In contrast to refined rosins, crude rosins contain volatile, neutral components (→ Terpenes), which may impose properties on them that resemble those of organic solvents.

Resin Acids. *Abietic acid*, the major component of *refined rosins*, has an acute oral LD_{50} in mice of about 2500 mg/kg. The acute oral LD_{50} of its *methyl ester* is > 5000 mg/kg in rats and rabbits. Resin acids were not mutagenic in the Ames test.

Refined rosins, original or chemically modified, have a negligible acute oral toxicity in rodents and guinea pigs, the LD_{50} values ranging from 4000 to 12 000 mg/kg; no acute dermal toxicity was found in rabbits for pale rosins.

On oral administration, *dark rosins* with a high phenolic fraction and *rosin esters* showed no acute toxic symptoms.

In longterm feeding studies with pale and esterified rosins on rats and dogs (90 days or two years), no toxic symptoms were observed at the 0.2 % to 1 % dietary level. Therefore rosins and their derivatives may be regarded as safe.

Generally, rosin acids, rosins, and their derivatives are not considered skin irritants. However, a small portion of the population shows an allergic response on patch tests. A high sensitization level was reported among printers exposed to gum arabic, a constituent of printing ink [146].

Fumes from rosins may cause ocular and bronchial irritation: ca. 80 % of humans exposed to products of wood rosin at a level > 0.12 mg/m^3 experienced severe irritation of the eye, nose, or throat. The TLV for rosin core solder pyrolysis products is 0.1 mg/m^3 aliphatic aldehydes measured as formaldehyde.

4.1.2. Hydrocarbon Resins

The acute oral toxicity (LD_{50}) of hydrocarbon resins in rats is generally greater than 5 g/kg body weight, and they were found to be nonirritating to the skin and eye under experimental conditions [147]. In the EEC directives, most hydrocarbon resins are not classified as harmful, toxic, or irritant to the skin and eyes. Handling of resins requires the usual precautions for working with chemicals. Inhalation of dust or fumes (the latter generated on heating or combustion) must be avoided. More specific information is given in the manufacturers safety data sheets.

Food legislation concerning hydrocarbon resins is regulated by many national authorities but will likely be harmonized with the requirements of the FDA and the EU. The main attention is directed to migration of residual monomers, oligomers, and additives that might contaminate contiguous media by diffusion, and to the stability of resin formulations under application conditions.

In the United States, numerous resins are CFR approved substances for the following:

175.105: Adhesives
175.300: Resinous and polymeric coatings
176.170: Components of paper and paperboard in contact with aqueous and fatty food
176.180: Components of paper and paperboard in contact with dry food
177.1210: Closures with sealing gaskets for food containers
177.2600: Rubber articles intended for repeated use
178.3800: Preservatives for wood.

In the EU, the use of materials intended – in their final state – to come in contact with products for human consumption is regulated by the framework directive 89/109/EEC, followed by several subordinate directives, one of which concerns the use of plastics materials, e.g., in food packaging (90/128/EEC). Implementation by the EU member states was required by January 1, 1993.

Monomers and additives are not allowed to be used for food packaging unless listed in the annexes of the latter directive (positive-list principle). Not all hydrocarbon resins have yet been covered there. Therefore, an industrial motion to enclose those resins in the additive list, among others of the IC type, was directed to the European Scientific Committee for Food, but has not yet been settled.

4.1.3. Polyamide Resins

Polyamide resins do not need to be labeled [EC guideline 79/831/EEC (classification, packaging, and labeling of hazardous substances), GefStoffV]. Some PA resins are licensed by the FDA for contact with foods.

If PA resins are used in the molten state, vapors can sometimes be formed, which do not impair general health or have any toxic effects, according to the current state of knowledge. Nevertheless, extraction of the vapors above processing equipment and adequate ventilation of the workplace are recommended.

4.2. Legal Aspects

Food legislation concerning resins is regulated by many national authorities, but will likely be harmonized with the requirements of the FDA (United States) and the European Community. The main questions are directed to the migration of residual monomers, oligomers, and additives that might contaminate contiguous media by diffusion, and to the stability of resinous formulations under the conditions applied (→ Foods, 4. Food Packaging, Chap. 8.1., → Foods, 4. Food Packaging, Chap. 8.2.).

In the *European Community,* the application of resins in the food sector will be regulated in connection with materials intended to come in contact with foods [148], [149] and with use of food additives other than colors and sweeteners [150]. Several directives that are especially relevant [151–153] have already been adopted.

In the United States, the use of resinous materials in contact with food is regulated in the Code of Federal Regulations (CFR) under Title 21 (Food and Drugs): Besides the use of resins, other additives such as stabilizers, fillers, and linker reagents are also addressed (e.g., Parts 172, 175, 176).

Natural gums, synthetic as well as natural terpene resins,indene coumarone,and petroleum hydrocarbon resins may be used as chewing gum bases with limitations (121.1059, 121.90). Terpene resins are permitted for coatings in direct use (e.g., coating of fruits) when the precursors originate from wood (172.280). In indirect applications, most resins (synthetically or naturally derived) may be used.

Petroleum hydrocarbons are authorized for indirect use as components of paper and paperboard (Part 176).

1. Introduction

Resorcinol [*108-46-3*], $C_6H_6O_2$, M_r 110.112, is a white crystalline compound with a weak odor and a bittersweet taste. Other names are 1,3- (or *meta*-) benzenediol, 1,3-dihydroxybenzene or dioxybenzene, and 3-hydroxyphenol. Resorcinol does not occur in nature as such. The first syllable of the name resorcinol is derived from the word resin because HLASIWETZ and BARTH obtained it by the destructive distillation of a natural resin in 1864 [1]. The structure of resorcinol

is similar to that of orcinol, 5-methyl-1,3-benzenediol [*6153-39-5*], which accounts for the second part of the name. Resorcinol has been produced industrially for more than 100 years.

2. Physical Properties [2]

The physical properties of resorcinol can be summarized as follows:

mp (101.3 kPa)	109.8 °C
bp (101.3 kPa)	276.5 °C
(1.33 kPa)	151.5 °C
Vapor pressure, liquid	
(110 °C)	0.10003 kPa
(150 °C)	0.99438 kPa

Resorcinol exists in at least two crystalline modifications (phases) [3]. At normal pressure the α-phase is stable below ca. 71 °C, whereas the β-phase is stable above that temperature up to the melting point. Transition rates from the α- to the β-phase between 72 and 100 °C are given in [4]. Both phases exist as rhombic – pyramidal crystals (Pna 2_1), but the unit cells differ in their dimensions: α-resorcinol: $a = 1.053$ nm, $b = 0.95$ nm, $c = 0.566$ nm; β-resorcinol: $a = 0.791$ nm, $b = 1.257$ nm, $c = 0.55$ nm. The unit cells of both phases contain four resorcinol molecules.

Interatomic distances in the resorcinol molecule are as follows: C – C 0.138 nm, C – O 0.134 nm, C – H 0.108 nm, O – H 0.102 nm.

Literature data on solubilities vary widely because of the presence of the α- and β-phases: according to [5], 198 g of resorcinol is soluble in 100 g of water at 50 °C; according to [6], 371.5 g is soluble in 100 g water at 50.4 °C.

The density of aqueous resorcinol solutions increases approximately proportionally to the resorcinol concentration.

3. Chemical Properties [7]

Resorcinol is a dihydric phenol and exhibits the typical reactivity of a phenol. Its most important reaction is with formaldehyde [*50-00-0*] to form phenolic resins (→ Phenolic Resins→ Phenolic Resins).

The hydrogen atom surrounded by the two *meta*-hydroxyl groups can be substituted much more easily than the other ring hydrogens. Compared to catechol [*120-80-9*] and hydroquinone [*123-31-9*], resorcinol has the highest reactivity toward formaldehyde.

4. Production

Resorcinol is produced commercially worldwide in only a few specialized plants. All of these plants use benzene [*71-43-2*] as the main feedstock (see Fig. 1). In Japan, resorcinol is produced in two plants (Sumitomo Chemical and Mitsui Petrochemical) via 1,3-diisopropylbenzene [*99-62-7*]. The United States (INDSPEC Chemical Corp.) and Germany (Hoechst) each produce it in one plant, using the "classical" route via 1,3-benzenedisulfonic acid [*98-48-6*] (see Fig. 2).

Figure 1. Resorcinol production reactions

Figure 2. Resorcinol production via sulfonation

4.1. Via Sulfonation of Benzene [8]

The sulfonation of benzene formerly led to the production of considerable amounts of waste because it was carried out with mixtures of sulfuric acid and sulfur trioxide. Excess sulfuric acid was precipitated with lime to form gypsum, which had to be disposed of in landfills.

Process Description. In the process variation used in Germany today, the sulfonation of benzene is carried out continuously with sulfur trioxide [*7446-11-9*] alone so that only small amounts of sulfuric acid are contained in the sulfonation mixture and the addition of lime is not required. After neutralization with sodium sulfite, soda ash, or sodium hydroxide solution, the sulfonation product disodium benzene-1,3-disulfonate [*831-59-4*] is mixed with excess sodium hydroxide and fed to an alkali fusion reactor at 320 – 350 °C. The endothermic solid-state reaction yields a white powder, consisting chiefly of disodium resorcinate [*6025-45-2*], sodium sulfite, and some excess sodium hydroxide.

Depending on the method used, the product of the fusion reaction is treated with either a small quantity of water (in this case, solid sodium sulfite which contains organic impurities, is obtained as byproduct) or a large quantity of water forming an almost saturated solution of the product. In both processes the dissolved disodium resorcinate is then reacted with sulfur dioxide, sulfuric acid, or hydrochloric acid to give resorcinol. The dissolved resorcinol is extracted with an organic solvent. The preferred solvent is diisopropyl ether [*108-20-3*], but benzene, 4-methyl-2-pentanone (methyl isobutyl ketone) [*108-10-1*], or others can also be used. The solvent is then distilled off, and crude resorcinol is purified further by distillation in vacuum. The byproducts of this process are small amounts of light ends, essentially phenol, as well as cresols and 3-mercaptophenol [*40248-84-8*], and small amounts of heavy ends, mostly oligohydroxybiphenylenes.

The salt solution remaining after extraction is processed further. When sulfuric acid is used to neutralize disodium resorcinate, sulfur dioxide and sodium sulfate [*7757-82-6*] can be recovered as byproducts from this stream.

4.2. Via Hydroperoxidation of *m*-Diisopropylbenzene

Benzene, together with a benzene – cumene mixture recycled from the alkylation process, is alkylated with propene [*115-07-1*] in the liquid phase by using an $AlCl_3$ – HCl complex as catalyst (→ Phenol, Chap. 4.1.). After addition of recycled *p*-diisopropylbenzene (*p*-DiPB) and triisopropylbenzene (TriPB), the alkylate is subjected to isomerization/transalkylation. In this step most of *p*-DiPB and TriPB are converted into *m*-diisopropylbenzene (*m*-DiPB). The reaction mixture is then separated by distillation into three fractions (benzene – cumene, *m*-DiPB, and *p*-DiPB – TriPB). The subsequent autoxidation of pure *m*-DiPB proceeds according to a radical chain mechanism. It is accomplished in a cascade of aeration reactors by using compressed air in an aqueous alkaline medium at 90 – 110 °C and 0.5 – 0.7 MPa to yield [1,3-phenylenebis-(1-methylethylidene)]bishydroperoxide (*m*-diisopropyl-

benzene dihydroperoxide, DHP) [*721-26-6*] [9] (see Fig. 1).

After an overall residence time of 6 – 8 h the oxidate contains ca. 20 % DHP and ca. 35 % *m*-diisopropylbenzene monohydroperoxide (MHP). The heterogeneous oxidate is subjected to phase separation. *m*-Diisopropylbenzene dihydroperoxide is then crystallized, centrifuged, dissolved in acetone, and fed to a cleavage reactor (→ Phenol). Higher concentrations of hydroperoxides lead to the above-average formation of byproduct and increased safety hazards. The main byproducts of oxidation are *meta*-substituted acetophenones and dimethylphenyl carbinols. The latter are converted to recyclable *m*-DiPB by acid- catalyzed dehydration and hydrogenation in downstream unit operations.

The cleavage of DHP to resorcinol and acetone [*67-64-1*] is carried out under acid catalysis (preferably with ca. 1 % H_2SO_4) in boiling acetone with a reaction time of 30 min [10, 11]. After neutralization, acetone is distilled off at normal pressure and resorcinol under vacuum. Further purification of resorcinol can be achieved by recrystallization or extraction. The overall process yield is ca. 75 %, based on benzene. Alternatively, cleavage of the oxidate can be carried out in the presence of hydrogen peroxide [*7722-84-1*]. In this case the carbinols formed as byproducts are subsequently oxidized to DHP and thus eventually also converted to resorcinol [12].

4.3. Other Processes

Koppers in the United States and Mitsui Toatsu in Japan have developed a process for manufacturing resorcinol from *1,3-diaminobenzene* [*108-45-2*], which is produced by the hydrogenation of dinitrobenzene [13]. The *dehydrogenation of 1,3- cyclohexanedione* [*504-02-9*] to resorcinol, described by British Oxygen, was further developed by Hoechst in Germany to a four-stage process [14]. The starting materials are acetone and methyl acrylate [*96-33-3*] or acrylonitrile [*107-13-1*]. Neither process has been commercialized. The direct hydroxylation of phenol with hydrogen peroxide, for example, has been investigated extensively, but it yields only catechol and hydroquinone (→ Hydroquinone, Chap. 4.2.) [15].

5. Environmental Protection

Resorcinol must not enter rivers, lakes, or groundwater. Since it is readily biodegradable, small amounts in a biological wastewater treatment plant do not pose any problems. If possible, resorcinol should be collected and returned to the producer. When resorcinol is present in the air in the form of dust, smoke, or vapor, it can be removed by air scrubbing with a small amount of water in a wet filter equipped with a demister (a once-through operation).

6. Quality Specifications and Analysis

Resorcinol can be identified by IR [16] or Raman spectroscopy [17]. The UV and NMR spectra are given in [18].

A violet color is produced when an aqueous solution of resorcinol is treated with an iron(III) chloride ($FeCl_3$) solution.

Freezing-point measurement is the most useful test for determining product quality [19]. Freezing-point depression indicates impurities, most frequently the presence of water. Because of the existence of two solid resorcinol phases, determination of the melting point as a measure of product quality is not recommended. Thus, for instance, the melting range of 110 – 113 °C given in [20], does not indicate the presence of impurities. Impurities are best determined by gas chromatography of a solution of resorcinol in toluene or ethyl acetate, using a fused quartz capillary column with a nonpolar stationary phase, and a flame-ionization detector (FID). Freshly distilled technical-grade resorcinol exhibits approximately the following characteristics:

Appearance	white flakes, crystals, or powder
Freezing point	min. 109.5 °C
Purity	min. 99.5 % (wt %)
Water content	max. 0.1 % (wt %) (Karl Fischer)
Phenol	max. 0.1 % (area/area) (capillary GC)
o-Cresol	max. 0.1 %
m-, *p*-Cresols	max. 0.1 %
Catechol	max. 0.1 %
3-Mercaptophenol	max. 0.2 %
Heavy ends	max. 0.3 %

Resorcinol becomes darker during storage especially when exposed to light, but this does not impair its suitability for most applications.

7. Uses

Resorcinol is used in industry as an intermediate. Worldwide consumption is about 40 000 t/a (1990), the primary consumer (more than 50 %) is the *rubber industry*. In the production of tires and other reinforced rubber products (conveyor belts, driving belts), resorcinol – phenol – formaldehyde condensates are used to enhance adhesion between cord and rubber (dip formulations, dry bonding agents). Furthermore, some rubber mixtures contain resorcinol to improve some properties after curing.

The second largest market for resorcinol (ca. 25 %) is in high-quality wood adhesives, which are made from resorcinol, phenol, and formaldehyde. These resorcinol – phenol – formaldehyde resins are especially suitable for the manufacture of laminated wooden beams – which must be to some extent waterproof – at ambient temperature. The first such use was in the manufacture of wooden aircraft propellers ("propeller glue").

Further uses include

1) A new process for producing the intermediate *m*-aminophenol [*591-27-5*]
2) Production of light stabilizers for plastics
3) Production of sunscreen preparations for the skin
4) Production of dyes (fluorescein, eosin)
5) Manufacture of special pharmaceuticals (e.g., acne preparations)

8. Transport Classifications and Occupational Health [21]

Transport classifications and labeling are as follows:

UN no.	2876
EC no.	604-010-00-1
IMDG Code	6.1/2876/III
RID/ADR	6.1/14 C
DOT/IMO	poison B

Resorcinol must be labeled "harmful" in the EC and *mindergiftig* (less toxic) in Germany, with hazard label Xn.

Occupational Health. No MAK value has been set. Exposure to resorcinol must be kept below 10 ppm or 45 mg/m^3 TWA (OSHA-PEL and ACGIH-TLV).

Toxicology. For oral toxicity, an LD_{50} = 301 mg/kg (rat) has been found. Tests with rats show fast excretion (> 90 % within 24 h), mainly via the urine as the glucuronide [22]. Resorcinol is less toxic than phenol or catechol if absorbed by ingestion or skin penetration. Ingestion of 8 g of resorcinol by a child resulted in hypothermia, hypotension, decrease of respiration, tremors, icterus, and hemoglobinuria.

In a two-year study, no evidence of carcinogenic activity was found when up to 225 mg/kg resorcinol in water was administered orally to male or female rats or mice. However, clinical signs suggestive of a chemical-related effect on the central nervous system, including ataxia, recumbency, and tremors, were observed in the rats and mice during the two-year study [23].

1. Origin, Deposition Mechanisms, Exploration, and Occurrence of Crude Oil and Natural Gas

1.1. Crude Oil

Crude oil is the name given to all organic compounds which are liquid under reservoir conditions. They can partly solidify at the surface after expansion and cooling. Petroleum is a mixture of hydrocarbons in varying proportions, which are accompanied by compounds of sulfur, oxygen, phosphorus, and nitrogen. Minor constituents are porphyrins, ash-forming metal compounds (usually sulfides of vanadium, nickel, copper, cobalt, molybdenum, lead, chromium, and arsenic), as well as inorganic salts, hydrogen sulfide, and – as a typical constituent of "crude oils" – water in varying amounts. The differing mixing ratios preclude uniform chemical and physical properties. Elementary analyses show average carbon contents of ca. 79.5 – 88.5 wt %, hydrogen contents of ca. 10 – 15.5 wt %, and impurity contents of up to a maximum of 5 wt %. Most crude oils are optically active.

The essential ingredients of the petroleum mixture are alkanes, naphthenes, and aromatics. The oxidation products naphthenic acids, terpenes, and phenols are also present in some cases. According to the predominant constituents, a distinction is made between *paraffin-based crude oils* and *naphthene- or asphalt-based crude oils.* If both hydrocarbon types are contained in considerable amounts in crude oil, it is termed *mixed-based oil.* The composition of crude oils on a worldwide basis includes more than 30 % paraffins, at least 40 % naphthenes, and ca. 25 % aromatics. Naphthene-based crude oils – that contain resinous and asphaltic substances – are frequently found in the upper level of the Earth's crust, mixed-based oils in the middle, and paraffin-based oils in the deeper zones.

Near the surface, the crude oils lose part of their volatile constituents. During this, with chemical processes participating, more or less solid residues are formed. Mainly ozokerite (earth wax) is formed from paraffinic crude oils and natural asphalts (→ Asphalt and Bitumen) from naphthenic crude oils.

For decades, petroleum has been mainly used as raw material for the production of engine fu-

els, lubricants, and fuel oil. Because of the complex compositions of crude oils, the chemical industry has developed many processes through which petroleum has become the basis of numerous plastics. In 1990, more than 10 % of world petroleum production was used in petrochemistry.

1.1.1. Formation

Despite a century's discussion with many contradictory opinions and intensive research, the formation of petroleum can still not be satisfactorily explained. The discussion on the inorganic formation of crude oils continues to this day. Russian experts, in particular Porfirev [56] do not exclude the fact that petroleum is formed from inorganic matter (metal carbides and superheated steam) even though it is generally agreed that the crude oils are predominantly of organic origin. The investigations of potential petroleum source rocks in the past decades have contributed considerably to this opinion. All deposits in the sedimentary basins contain organic residues of terrestrial, limnic, fluvial, and marine species, whose conversion under anaerobic conditions leads – as can be demonstrated chemically – to bitumen (soluble in organic solvents) or kerogen (insoluble). Such rocks are classified as source rocks according to the amount of organic material. In clastic sediments, a petroleum source rock should contain at least 0.5 wt % and in carbonates at least 0.3 wt % of total organic carbon (TOC). A source rock with a TOC value of more than 4.0 wt % is classified as excellent [57].

The organic substance originates from photosynthesis that started on a major scale 2×10^9 years ago. Welte [58] has calculated that in the course of the Earth's history 6.4×10^{15} t organic carbon (C_{org}) has been produced. Only 18 % of the organic carbon, however, has contributed to the genesis of petroleum, 82 % is bound in the sediment as carbonate. The ratio of C_{org} bound to carbonate to C_{org} bound to petroleum is 11 000 : 1. The organic origin of the petroleum can also be deduced from the observation that crude oils are cracked at temperatures above 200 °C to methane and graphite. The simultaneous occurrence of copper, nickel, vanadium and molybdenum (that are also detected in the sapropel) in crude oils is also in favor of its organic origin. Sporadic occurrences of small oil reservoirs in volcanic or in magmatic-metamorphic rocks that have repeatedly been quoted by the "inorganic" protagonists as counter-evidence are always in connection with local elevations of the basement. It can be assumed that the crude oil has migrated from deeper-lying source rocks in intercalated volcanic strata in a higher position between sediments or by lateral migration where there is juxtaposition with magmatic-metamorphic reservoir rocks.

Crude oils are formed principally from phytoplankton and bacteria; up to the Silurian period from lower plants, e.g., blue and green algae, and from the Devonian period from higher forms that occur in increasing amounts. The fats (lipids), proteins, pigments, and amino and nucleic acids formed from them are the starting materials for bitumens.

A prerequisite for the formation of oil is that the organic material lying at the bottom of the sea or lake must be sedimented in the absence of oxygen, so that it cannot be decomposed and lead to the formation of kerogen. Such conditions exist, e.g., in eutrophic calm waters at great depth where the water in the sediment no longer contains dissolved oxygen. A reducing hydrogen sulfide medium prevails. Ideal prerequisites for such conditions are present in sapropels in which the organic matter is decomposed, decayed by anaerobic bacteria. The majority of the organic matter, however, is oxidized and recycled as CO_2.

In the course of the Earth's history, source rocks have been formed in various anoxic zones:

1) *In nonmarine lakes*, a uniform warm climate with little inflow of oxygen- containing water is the precondition for source rock formation. Lake Tanganyika is an example.
2) *In closed inland seas with a positive water balance* (water inflow exceeding rate of evaporation), anoxic conditions arise in warm climatic conditions, at a great depth, and excess water. The Black Sea with its deep zones free from currents and its bays free from breakers is an example.
   With a *negative water balance*, an oxygen excess arises, preventing source rock formation. The Red Sea and the Dead Sea are examples of this.

3) *The ascent of marine currents from greater depths* to the surface leads to the substantial consumption of the scarce oxygen present in these currents as a result of the biological productivity near the surface. From the organic residues that sink in the deep water lacking in oxygen, source rocks have been formed. Examples of this occur off the Southwest African coast (Benguela current) and off the west American coast (Humboldt current off Peru).
4) Source rocks are formed in the *open ocean* as a result of global climatic warming in association with the large transgressions. The many thick source rocks in the Jurassic and Middle Cretaceous periods are attributable to this.

An important factor in source rock formation related to the transgressions of the oceans is the transport of the organic residues from the energy-rich zones into regions of calm water lacking in oxygen. This is supported by the adsorption of organic material onto fine clay particles, which sink to the sea floor in calm regions and compress the organic material content of the sediment. Anaerobic conditions can prevail only a few centimeters below the surface of argillaceous deposits. Since ca. three quarters of all argillaceous and carbonatic sedimentary rocks contain organic carbon, the applied exploration usually assumes that not only typical sapropels but all sediments, with a fairly high content of organic matter, are to be regarded as potential source rocks for hydrocarbons.

A high sedimentation rate with a large proportion of coarsely clastic material, on the other hand, dilutes the content of organic carbon and leads to source rocks of low quality, if to any at all.

Actuo-geological observations on hydrocarbon groups from recent marine deposits off the Californian coasts and comparative infrared spectroscopic studies on oils in the Pliocene Los Angeles Basin indicate that at the time the oil was formed in the Pliocene epoch, water and sedimentation conditions must have prevailed that are similar to those in the offshore regions of the sea nowadays [59].

Even in shallow depths down to 1000 m and temperatures up to 50 °C the organic material embedded in the sediment is converted to kerogen. This *diagenetic process* intensifies with further covering and sinking as well as with temperature rise as a result of heating from the Earth's interior. This process, known as *catagenesis,* proceeds at depths of 1000 – 5000 m and temperatures up to a maximum of ca. 175 °C (Fig. 1). During catagenesis the organic material dehydrogenates, with the formation of methane and hydrogen as well as $C_{13} - C_{30}$ liquid hydrocarbons with increasing temperature. Oxygen and hydrogen escape more rapidly than the carbon and nitrogen from the source rock and so the relative carbon content increases. The H : C ratio decreases with increasing temperature [57].

The conversion of organic material by pressure and temperature occurs over geological ages. The biochemical processes, which are still not known in detail, involve the action of reducing bacteria and the catalytic action of the rocks. The conversion can be described as a function of temperature, time, and pressure by modeling (see [60]). The temperature is the most important factor. According to these ideas, the conversion of the organic matter included in the source rock starts even at low temperature with the intensive contribution of microbes and leads to the formation of proto-bitumens. Methane is formed in minor amounts as a byproduct of the microbial conversion. Through further settling, as a result of increased sediment cover or through heating as a result of subsurface magma intrusions, the temperature of the source rock rises and, by liquefaction of a part of the primary bitumen, leads to true petroleum formation.

The simultaneous compaction of the argillaceous source rocks, and the recrystallization of the clay minerals into more stable forms with lower water content cause large amounts of pore and crystal water to be released. With this squeezed-out dehydration water, the newly formed oil migrates according to the geothermal gradient – at depths ranging between ca. 1000 and 3000 m (the so-called oil window) – possibly in dissolved form or as small droplets or bubbles, out of the source rock and into the overlying or adjacent reservoir rock (see [61]).

This primary migration of oil droplets from the source rocks to the petroleum reservoir rocks can proceed laterally and, in particular, vertically. The low-molecular, possibly gaseous hydrocarbons function as a propellant. While

lateral migration probably occurs by capillary paths, vertical migration through impermeable strata is mainly based on fine fissures that close afterwards [59]. If the thermal stress on the oils in source or reservoir rocks proceeds further, the degradation and break-up of the high-molecular hydrocarbons by chemial maturation leads to ever smaller and more stable compounds. Thus, a natural cracking of the petroleum occurs. Accordingly, paraffin-based oils are found mainly in deeper regions of the Earth's crust. The maturation process concludes with the conversion to methane.

During this maturation of the oils already present, a further part of the organic matter that has remained fixed is possibly converted into petroleum. According to [60], the temperatures necessary for the genesis and maturation of the petroleum are closely related to the geological time available for them. Thus, according to Russian ideas, ca. $40-50\times10^6$ a are required for the start of petroleum formation at an earth temperature of at least 60 °C. The Californian deposits mentioned, though, have formed at temperatures above 100 °C in only $1-2\times10^6$ a [62].

1.1.2. Formation of Deposits

Deposit formation is the concentration of infinite numbers of oil droplets which form in source rocks and are then squeezed out of them to economically exploitable accumulations. Deposit formation is the result of oil migration. The oil particles move during primary migration from the argillaceous source rocks into the porous reservoir rocks, which usually lie at a higher level. A considerable fractionation of the crude oils can occur even during this movement as a result of selective filtration, adsorption, and condensation [63], [64].

1.1.2.1. Migration

In many cases, however, the true concentration of deposit formation occurs only through migration in the bedding or horizontal secondary migration, i.e., through movement and accumulation within the permeable reservoir horizons. With favorable facial conditions, lateral migration can be very important for deposit formation. It can occur over distances of 10 km to a maximum of 100 km. With changing facies, differential migration can occur, by which the lighter hydrocarbons migrate to the higher reservoir beds. During the course of this, the oils experience a certain buoyancy in relation to the formation water present in the reservoir rocks because of their lower density. The oil is therefore concentrated in the highest zones of the reservoir horizons, which are sealed above by mudstones or salt beds. A gravity differentation of petroleum over edge water within the permeable reservoir rocks then occurs which corresponds to the different densities of the individual components. Provided gravitational separation is not prevented by capillary forces due to small pore diameters, the edge water limits the oil column to the botom of the reservoir (oil – water contact). If the oils are supersaturated with gas, a gas cap forms over the petroleum.

Possible reservoir rocks are permeable and porous sandstones and limestones. They have average porosities of ca. 10 % to a maximum of 40 %. The quality of reservoir rocks is determined, aside from their pore volume, by their permeability, which is of decisive importance for the production capacity of wells.

Petroleum and gas deposits can occur in all geological formations, starting from the Cambrian period, provided reservoir rocks are available that are accompanied or underlain by source rocks of appropriate maturity. Also the reservoir rocks must possess trap structures from the overlaying of sealing horizons, such as clay and salt beds. It is also important that the structural traps were already present at the time of oil formation and survived during the subsequent geological periods.

1.1.2.2. Reservoir Rocks

The quality of deposits is greatly affected by the type of reservoir rock.

Wind-blown sands, for example, form the good gas reservoir beds of the Rotliegendes. They spread from England to Poland over an area of 1000 – 3000 km^2 with thicknesses of up to 200 m and maximum porosity up to 20 %. *Fluvial sands* of meandering rivers can have net thicknesses of 6 – 75 m. The Triassic sands of Prudhoe Bay with reserves of 2.8×10^9 t oil belong to this type. Both *alluvial fans* such as the Cretaceous sands of the Sirte Basin in Libya and the *beach and barrier sands* parallel to the coastlines are good reservoir beds. The latter include the Jurassic Piper field (United Kingdom). The *marine platform sands,* which occur as transgressive or regressive sequences, are equally good reservoir beds. *Deep-water sands,* occurring as so- called deep-sea fans and turbidites, certainly spread over hundreds of kilometers, but are of variable quality. This reservoir type includes the Pliocene Sands in the Los Angeles Basin with a thickness up to 700 m and the Paleocene Sands of the Viking Graben in the North Sea.

Carbonate reservoir beds can be of very differing quality. Thus *reefs* or *reef limestone debris* can have excellent reservoir properties as in West Texas or Alberta/Canada, with net thicknesses of 170 – 200 m, but they are mostly of limited extent and variable quality. The *chalk* forms only average-quality reservoir beds. Mainly composed of coccoliths, the chalk is thin-bedded. The production engineering of the Austin Chalk in West Texas, the Ekofisk field in the Norwegian North Sea, or the reservoir of Reitbrook (Hamburg) is difficult. Owing to their low permeability, these deposits can be extracted profitably only in conjunction with very fine fissuring.

1.1.2.3. Trap Structures

The type of trap structure encountered strongly depends on the worldwide or regional tectonic processes in the Earth's crust. Movements at the plate edges lead to individual stress patterns with a variety of structural phenomena as the result of forces of contraction and expansion. The structures can, therefore, be of various sizes and shapes [65], [66]. The principle trap structures, as listed below, can also occur in combination.

The types of structure possible as traps for petroleum and natural gas can be of very different origin (see Fig. 2). There are anticlines (a), tiltings, faults (d), salt intrusions, and discordant overlappings, and sometimes synsedimentary facies differentiations which arose during the deposition of the beds. Permeability barriers, arising as a result of secondary recrystallization and the formation of new minerals in the pores, laterally seal the reservoir in such a way that a special form of the facies reservoir is formed. This can often be observed in conjunction with faults. The most important tectonic traps are the saddle-shaped anticlines and flat, oval mound structures as well as monoclines originating from antithetic faults. Reservoirs in association with overthrusts are usually arched in the frontal zone and sometimes enrolled. They are known as rollover structures. The first reservoirs discovered were found in association with salt domes (d), where various kinds of structural traps are possible on the flanks and the top of the dome. In the case of discordance reservoirs (c), porous horizons are sealed off after tilting and partial removal of horizontally deposited younger sediments. Other typical facies reservoirs are the reefs (b), which are usually composed of corals, as well as traps which have arisen, e.g., through the argillation of a sandstone with reservoir characteristics. In addition, there is a variety of special forms and combined reservoir types. In all of these cases, it is common that porous reservoir horizons in their top zone are covered and transposed with sealing by clay rocks and salt layers.

1.1.3. Oil Exploration

The potential for petroleum and natural gas present in a sedimentary basin must be proved by exploratory wells. The total costs of the wells – which rise exponentially as a result of ever increasing depths, extreme environmental conditions, and continually increasing costs of equipment and personnel – require intensive and expensive scientific preliminary exploration. Aside from the geologists, the geophysicist and, with growing importance, the geochemist, have made themselves equally valuable as exploratory experts. No drilling project is commenced unless these experts, after having made their profitability calculations, have given their approval. After calculation of the risk capital for the exploration phase, an analysis must be made of the receipts and expenditure over the whole operating life of the expected oil field: in other words, the driving force for exploration is the return on investment. Despite all care, the risk of sinking dry wells remains high. The ratio of discovery wells to dry wells, from 1 : 8 to 1 : 6, since the 1950s has not greatly improved. The reason is that exploration advances into new basins (or parts of basins) and to greater depths. The ratio is very much more favorable, for instance, in the Norwegian North Sea, where of about 300 exploration wells, of which about half were wildcats (i.e., wells drilled in regions not known to be productive), more than 100 were oilbearing. The success rate was 1 : 3.5. It is therefore necessary to reconstruct the conditions of formation of the hydrocarbons in the chronological and regional framework and to check whether potential reservoir rocks are in trap position for oil or gas. The seismic reflection method is the central element of modern exploration and crucial for almost every well. This method has been operated and continually developed for more than three decades. It is supported by a series of geological, geophysical, and geochemical methods that are used according to the degree of knowledge or development of a region and according to the problems. In an already well-known region – aside from studies on geological facies and thickness of the rock sequences – investigations start with seismic reflection measurements. In contrast, in areas which geologically are still little explored or with very deep parts of a basin, these measurements usually conclude the geophysical preparation.

1.1.3.1. Geological Investigations

In areas which are still little explored, especially on land, geological surface investigations are

used for the first assessment and possible delimitation of prospects and nonprospects. The prerequisite is merely that the stratigraphic sequence outcrops at least partly at the surface and is accessible. In the present state of exploration, the number of less explored areas has greatly diminished. In the 1980s, the number of sedimentary basin prospects is ca. 700. Of these, 350 are at least partly explored. In the remaining sedimentary basins, preliminary geological investigations have generally been carried out which permit conclusions on the nature and thickness of the sediments. From *satellite images,* precise maps are available for all parts of the world in which geologists enter their findings. Geodetic methods are becoming increasingly less important. In regions with poor vegetation, the satellite image also permits conclusions on the geology. Later – when checked and consolidated during the course of geological field surveys by a smaller or greater number of transverse profiles – these conclusions suffice to enable statements on the thickness, facies, and age of the rocks. If the results of the field surveys show that criteria for an oil prospect are present, special *examinations of rock samples* are necessary in addition to *stratigraphic investigations* in order to identify source and reservoir rocks and to provide evidence of clay as well as of evaporites being important as the seal. The evidence of oil and gas as well as asphalt traces in the rock samples alone is not sufficient to predict the presence of oil deposits. Asphalts are residues of originally liquid bitumens that, as a result of the break-up of a reservoir, have moved and oxidized near the surface. Asphalt traces can, therefore, be an indication that oil has formed and migrated. Reservoirs, however, can be left as fairly deep structures below thick, dense sediments, even when younger reservoirs have been destroyed, e.g., by uplift, tilting, and erosion.

1.1.3.2. Geophysical Investigations

1.1.3.2.1. Potential Methods

The nonseismic geophysical methods (potential methods) include electrical, magnetic, and gravimetric methods. They are used both individually and combined, for the first exploration of sedimentary basins. Since gravimetric and magnetic measurements can be made from an aircraft, they are a rapid and inexpensive tool of petroleum exploration.

Magnetic Measurements. These measurements are based on the phenomenon that rocks differ in their magnetic susceptibility. It depends on their content of magnetic minerals such as magnetite or ilmenite. The crystalline basement would cause no marked anomally, owing to the uniform distribution of magnetic minerals within them. Sediments, on the other hand, differ in their susceptibility according to the proportion of such minerals in the strata. The changes of the Earth's magnetic field are recorded with the aid of proton magnetometers and give, for example, indications of the shape and depth of the crystalline basement or of volcanic or magmatic intrusive bodies. *Aeromagnetics* was developed in World War II to detect submerged submarines. The measuring instruments are accommodated in the wingtips of the aircraft or towed behind on cables. In their basic version, the measuring instruments are coils through which current flows. The applied magnetic field is altered by the terrestrial magnetic field and the resulting anomaly is recorded.

Gravimetric Measurements. Gravimetric measurements are used to measure the changes in the Earth's gravitational field. Because of the different densities of rocks, beds of relatively low density, such as salt rocks, with negative anomalies can be demarcated from rocks of higher density, such as intrusives or quartzites, with positive anomalies. As a result it is also possible to detect blocks of identical rocks that are displaced tectonically by faults. The typical measuring instrument is the spring balance, whose spiral spring shows a different extension according to the density of the rocks. The extension is recorded and interpreted (Fig. 3). Aerial gravimetry, combined with aerial magnetics, is a rapid and cheap method of reconnaisance survey for the petroleum exploration of extended areas.

Gravimetric methods are increasingly used again for the solution of special problems. Computer model calculations can be carried out which lead to considerably improved conclusions. Thus gravimetric measurements are an

Figure 3. A) Principles of gravitational surveying; Points 1 – 9 represent observation stations where the gravity meter is installed. At these points the attraction of the gravitational force is measured. B) Negative gravity anomaly over a subsurface salt dome with associated oil accumulation; a) Salt dome; b) Cap rock; C) Positive gravity anomaly over an igneous uplift or "buried bill" with an oil accumulation in the overlying sediment

important means for detecting petroleum reservoirs at the flanks of salt domes; for the definition of the drilling and casing program and the allowed deviation for deep gas wells; and also for the interpretation of seismic surveys near salt domes, where the reflections are disturbed by the salt, in order to clearly determine the salt flanks.

Geoelectric Measurements. Geoelectric measurements of the natural Earth currents (tellurics) in the form of magnetotellurics have not fulfilled the hopes placed in them. The numerous interference factors in the industrial countries, such as electrical energy in cross- country transmission lines and on railway lines are as disadvantageous as the large spread of the results. Magnetotelluries are therefore only rarely used.

1.1.3.2.2. Seismic Methods

Since the 1970s seismic methods have become the most accurate and most frequently used exploration methods. This is mainly due to digital recording and the many processing and interpretation programs available. If in the past, seismics was a subsidiary science of geology, today it must be ranked of equal importance alongside it. The seismic methods permit very accurate conclusions on the stratigraphic sequence

and depth of geological beds. These methods measure the transit time of artificially generated elastic waves. The waves have usually been generated by the detonation of explosive charges placed in boreholes (Fig. 4). Apart from this, other energy sources also are used nowadays. The *vibroseis method,* has become established whereby a steel plate mounted below a truck is pressed by the weight of the truck onto the ground. This transmits controlled vibrations of a given frequency that are produced by a vibrator installed in the truck, to the subsoil. Four to six vibrator trucks operate simultaneously. With this method, measurements can be performed on roads and tracks and therefore in populated areas. It is also more rapid than explosion seismics, and cheaper.

The elastic waves spread in all directions and at bed boundaries, e.g., between claystone and sandstone or sandstone and carbonate. They are partly refracted and partly reflected to the surface by the echo sounder principle. The velocity of these seismic waves through the various geological strata is a measure of the type of rock and depends on the rocks' elasticity and density (ca. 1000 – 2000 m/s in loose rocks and up to 6000 m/s in compact rocks). The more accurately the actual velocity in each bed is known, the more accurately can the depth of the reflection be calculated. Computer model calculations provide very useful approximations. There are two different methods: the reflection seismic method and the refraction seismic method, the latter was used almost exclusively until the 1930s. The refraction seismic method is still used nowadays only for wide-area surveying of deep-lying horizons, but is also called in for the determination of sonic velocities in the rocks and to solve special problems.

Seismic Refraction Method. In the seismic refraction method a part of the energy waves is refracted at the refraction horizon, similar to light being refracted at the interface between water and air. Some of the refracted waves then continue to run along the bed boundaries and in the course of this generate other waves that are refracted again to the surface. The measurement is of the transit time from the detonation at the energy center until the refracted wave impinges on the geophones set up on the surface at distances of up to ca. 25 km. The seismic refraction method requires large explosive charges with the geophones at a relatively large distance and enables a relatively large depth of penetration.

Seismic Reflection Method. The seismic reflection method uses, in contrast to the refracted wave, the waves directly thrown back by the reflecting horizons. Depending on the depth of the reflecting horizons, the waves return to the Earth's surface after increasing time intervals and are received by groups of geophones systematically laid out on the ground. They are then converted to electromagnetic impulses and recorded on magnetic tapes in complicated digital recording equipment. Recording the seismic signals on magnetic disks – having already been pretreated in the recording truck by amplification, filtering, and balancing of the vibrations – enables corrections to the raw data and various investigations of the signals with simultaneous suppression of the interference energy (noise) to be carried out at the geophysical playback centers. From the transit time found for the emitted and reflected waves, the depth of the reflecting bed can be determined, provided the velocity of the rock beds passed through, which often shows rapid regional variations, is known. The depth is then half the product of velocity and transit time. Indications of the velocity of the seismic waves come from detailed calculations of the refraction and reflection seismic methods, from seismic well-logging, and directly from a geophone being lowered on a wine line in the bore hole. The geophone is positioned at the boundaries of rock units and receives the waves produced in the usual manner off the well site.

Aside from the compression waves which have up until now been used almost exclusively for scanning the structural conditions in the subsoil, *shear waves* also are gaining increasing importance today. They enable conclusions to be made on the petrographic nature of the rocks and their contents. The combination of compression and shear waves permits at least approximations to the porosity of a reservoir rock and to the pore content.

Seismic Measurements in Offshore Regions. The reflection seismic measurements can also be used in offshore regions. The seismic method based on explosives previously used, has been abandoned and replaced because of the great en-

Figure 4. Reflection seismic surveying technique with two reflecting horizons, A and B

vironmental damage, especially where a large fish stock exists; at the same time the airgun method has established itself. In this method highly compressed air is suddenly released. With the large number of available recording vessels, seismic companies not only carry out commissions to order but, in all seas, carry out self-financed measurements which they then offer for sale to the oil companies for reconnaisance purposes.

Three-Dimensional (3 D) Method. In exploration seismics, the *line method* has hitherto been used almost exclusively. According to the exploratory problem definition, individual profiles spaced at a distance of 500 – 2000 m from each other are intersected by crosslines having the same spacing. The 3 D method, which is almost routine in the development of proved deposits, is also being used more and more in exploration. The groups of geophones are placed at profiles with distances of 25 m and the waves are generated by explosives fired from various sides. The digitally recorded results are processed and corrected, as in the line seismic method, and subsequently transmitted to work stations. Because of the small distances between profiles and the possibility of assembling profile lines according to one's own ideas via shot points of neighboring lines (random line), the interpretation of the reflection horizons leads to increased precision. Because of the high cost of equipment – several thousand geophones are required for the geophone installation – and the large number of staff used – up to 350 members – the method is very expensive. It pays, however, especially during development of a productive area, since as a result of the close surveying, false interpretations and consequently false structural descriptions are restricted or even avoided. Characteristics of a 3 D measurement are given below:

Area of survey	300 km^2
Surveying party size	140 employees
	32 vehicles
	1000 tracks
Geophones	14 400
Optical-fiber cable	71 500 m
Bore holes	15 076
Drilling meterage	157 183
Scanning points	480 000
Cost	ca. $\$ 7.5 \times 10^6$
Cost per km^2	\$ 25 000

1.1.3.3. Geochemical Investigations and Determination of Coalification on Cutting Samples

Geochemical investigations and determinations of coalification have become increasingly important. They are used as indicators of maturity and prospectiveness for potential source rocks and for settling questions about migration paths and the origin of crude oils and natural gases. These determinations are carried out partly with rock samples from geological field surveys or partly with rock sequences from boreholes. *Coalification investigations* serve to determine the maturity of a source rock. If it is established that source rocks are immature then any further exploration activity is often abandoned. Coalification studies, preferably reflection photometric measurements, are applied to vitrinite, which is present both in coal seams and in other sedimentary rocks. Depending on the coalification gradients, which show regional variations, the coalification and the vitrinite reflection increase with growing depth while the volatiles content simultaneously falls. From the peat to the graphite stage, the mean reflection values range from ca. 0.2 % – 10 %. According to the carbon ratio theory, the formation and release of oil is restricted to the previously mentioned "oil window" with a coalification range of ca. 0.45 – 1.25 % vitrinite reflection (subbituminous coal to high volatile bituminous A coal stage). Below the oil window light oils and condensates can still be formed and, at greater coalification, natural gases. By *chemical investigations* on source rock samples, fairly reliable conclusions on their degree of maturity are possible. *Optical parameters* are also used. Here the change of color of the dispersed organic material in the sediment on heating is determined. The optical studies have little significance and should be used only together with chemical or pyrolysis data. *Pyrolysis,* performed on a large number of rock samples, is very important for the analysis of kerogen. The Rock – Eval pyrolysis tester provides rapid determination of the type and degree of maturity of the kerogen together with a direct determination of the hydrocarbon potential. The results of the investigation can be used as geochemical logs directly at the well for the determination of the hydrocarbon potential and the maturity. The comparison of several boreholes enables excellent geological/geochemical correlations in a region.

Carbon-isotope analyses of natural gas components are routine in hydrocarbon exploration. These makes use of the close connection between the $^{13}C : {}^{12}C$ ratio in methane and the maturity of the organic matter from which the methane has been formed. It is possible, by isotopic analysis of gases, e.g., gases from cuttings from boreholes, to decide whether these gases have been formed indigenously in the horizons just drilled through or have risen from deeper strata. With isotope investigations, for example, it was possible to demonstrate that the natural gases accumulated in the large fields of Northwest Germany, the Netherlands, and southern North Sea originate from the coal seams of the Pennsylvanian system [67]. The carbon-isotope ratios of petroleum gas also enable reliable estimates of the stratigraphic assignment of the corresponding source rocks [68]. So-called *chemofossils* enable conclusions both on the deposition medium and on the "thermal history" of the sediment. These geochemical fossils, also known as biomarkers, are molecular structures of organisms in the form of lipids (e.g., fats, waxes) and porphyrins, etc., that have undergone only small changes during their transformation to kerogen. The main features of their chemical structure are still present.

Geochemistry has also been concerned intensively with the *primary migration* of crude oils, which for a long time was difficult to interpret. It is assumed that pressure built up in the sediment due to the decomposition of kerogen which led to the formation of microcracks, through which the hydrocarbons could escape from the source rock. They are transported with low-molecular hydrocarbons as propellant in the direction of the pressure gradient to more permeable rocks. An important instrument of exploration in future could be the geochemical modeling of sedimentary basins. The amounts of petroleum which have formed in a basin, migrated, and finally concentrated in a reservoir are calculated using computer methods. This calculation is carried out in close collaboration with the geological development and not only takes into account the sedimentation and facies distribution, but also the settling and the related rise of temperature, as well as the uplift phases with erosion of reservoirs already formed. A three-dimensional ki-

netic model has attracted attention [69]. It is based on a set of differential equations for energy and mass balances that describe the course of various geological processes. The physical parameters, such as porosity and permeability, and the thermal sequences are selected from available lithological data and, as knowledge increases, can be adjusted iteratively.

1.1.4. Occurrences, Production, and Reserves

The petroleum occurrences are associated with the sedimentary basins of the Earth. Their distribution is in no way statistical. Even their tectonic classification is very diverse and shows that deposit formation is not associated with only certain types of basin (Fig. 5). The largest petroleum occurrences lie in basins that have subsided considerably for instance as a result of the continental drift – approximately from the Jurassic to the Middle Tertiary period – and, owing to a lack of contact with oxygen-rich waters of polar origin and to a simultaneously warm climate with high, oxygen-reducing water temperatures, have preserved large amounts of organic material in the anoxic medium. The reserves in older geological formations are relatively small. The reason may be that there were fairly small amounts of organic material in the shallow seas of the epicontinental region during the flooding by the worldwide transgressions. But the smaller reserves in older formations than those of the Mesozoic era may also be the result of thermal evolution (conversion of oil into gas), the destruction of the reservoirs or their sealing horizon by tectonic events and erosion. The sedimentary basins with prospects are nowadays distributed both over the continents and over the regions of the continental shelves covered by the seas (Fig. 6). The methods of exploration and development are in both cases the same, for offshore wells the means of transport and technical installations are adapted to the water medium. The difference lies in the greater costs for offshore wells and production installations.

Apart from the classical offshore fields in Lake Maracaibo (Venezuela) and in Baku (Caspian Sea) that were already developed in the 1930s with modified onshore installations, offshore exploration and production achieved increasing importance only in the 1960s. Technical developments then became necessary that enabled deposits to be developed even at a depth of more than 1000 m water. In 1983, on the west coast of France, a well was drilled to almost 2000 m at a water depth of 1714 m. Such depths of water cause difficulties for production, which then is only possible by means of an underwater completion. This means that the production equipment is totally installed on the ocean floor and must be maintained by divers. The deepest producing field is the Jolliet field in the Gulf of Mexico. It produces from a depth of 535 m of water and is equipped with a tension leg platform, i.e., a floating platform that is fixed to the ground by steel wire ropes. In 1992 the Snorre field in the Norwegian North Sea also went into production by means of a tension leg platform at a depth of up to 350 m of water. Further production installations according to the tension leg system are being prepared up to ca. 1000 m (Auger and Marlin fields). Owing to high investment costs, the systematic recovery of hydrocarbons at great depths of water, in particular on the continental slope, depends on the development of the market price of crude oil.

1.1.4.1. Production and Reserves

The prices of crude oil collapsed in the second half of the 1980s. OPEC saw a possibility of stabilizing the prices only by fixing production quotas. These efforts, however, had no particular success. The control of production by OPEC as well as other economic measures in producing countries outside OPEC, influence production in such a way that the annual production data do not give a clear picture of the productivity of a producing country. Rather, the cumulative production gives only an impression of the geological and technical capacities (Table 1). For better comparison, the annual production for 1989 for the region concerned is indicated. World oil production for the year 1989 was 3.434×10^9 t. In 20 years, it rose only by ca. 20 %. In view of worldwide industrial development this is only a moderate increase that is attributable in part to energy saving efforts which started with the 1973/1974 energy crisis. The ranking of the producing countries for 1989 shows that the Middle East states Iran,

Figure 5. Geotectonic classification of petroleum occurrences

Figure 6. The sedimentary basins of the Earth with the most important production areas

Iraq, Kuwait, Saudi Arabia, and the United Arab Emirates lead the list of producing countries with a production of 922×10^6 t, followed by the Soviet Union with 668×10^6 t, and the United States and Canada together with 525×10^6 t. Following behind are South and Central America (380×10^6 t), Asia/Oceania (365×10^6 t), Africa (350×10^6 t), and Europe (223×10^6 t). The production from offshore fields was about 25 % of world oil production [70]. The proved world oil reserves rose to ca. 164.30×10^9 t through development, in particular, of offshore fields. Compared with reserves published in the 1970s (92.40×10^9 t) this is an increase of >80 %. If the probable reserves determined according to the Gaussian distribution curve are added, then there are currently 240×10^9 t petroleum to be expected. Compared with the production of ca. 3.4×10^9 t in 1990, this gives a ratio of 72 : 1. Thus the ratio of 30 : 1 existing for decades has more than doubled. Even taking only the proved reserves into account, the ratio is about 50 : 1. There may be various reasons for this. One could be the rapid sequence of discovery and development of large deposits – above all offshore. These include new discoveries in East Venezuela and in the Brazilian Campos Basin, as well as in the Russian North Caspian Basin and in Saudi Arabia. Large reserves have recently been developed in the Tarim Basin (West China) and in the Papua Basin of New Guinea, in which up until now no eco-

nomic oil discoveries have been known. Another reason is certainly the nature of the recording or evaluation of the proved reserves. The new assessment is based on the newly proven or re-evaluated reserves in the oil fields, larger extent of the deposits, or improved oil recovery. At the World Petroleum Congress in 1990, a rise of the reserves by 45×10^9 t to more than 164×10^9 t, was reported, i.e., a rise of ca. 33 %. Of this, ca. 32×10^9 t are apportionable to the Middle East and only 3×10^9 t to North and South America. Other authors quote a larger or smaller rise than this. The reason for this may be that, in addition to the newly developed reserves, new evaluations of the fields have been made in which, apart from the proved reserves, probable and possible reserves have been accounted for. The reserves according to MASTERS et al. [71] listed in Table 1 represent, despite all uncertainties, a reliable order of magnitude. The size of the increase in reserves from new discoveries also reflects the number of successful exploration wells. As stated above, the saturation of the petroleum market since 1985 has led to a drastic reduction of exploration activity. If in 1984 in the western countries, 1250 seismic crews and 6500 drilling rigs were in use, their numbers had fallen in 1989 to 447 and ca. 1924, respectively (1990: 2057, 1991: 1896). A speeding up of exploration depends on the general improvement and stability of prices and availability of reserves in the important consumer centers. The further prospects for success in petroleum exploration are limited to where the assumed profitability for foreseeable future ends or when the natural deposit potential of liquid hydrocarbons in the subsoil of the earth is exhausted. The two aspects are closely interlinked, since the estimation of potential reserves and even the definition of a deposit are determined by profitability factors. The ca. 77×10^9 t of conventional crude oil still to be expected according to the most recent estimates must be supplemented by the reserves from very heavy oil deposits and oil (tar) sands (→ Tar Sands), which can be assumed to be at least 100×10^9 t. An accurate demarcation from the "conventional" crude oils listed in Table 1 ist not possible, since MASTERS et al. [71] also take into account the reserves between 10° and 20° API (for a definition of ° API, see → Oil Refining, Chap. 7.1.), which other authors include in the low-quality heavy oils. The heavy oil and bitumen deposits are found to the extent of 87 % in Canada (Athabasca, Cold Lake, Peace River), the CIS (Volga – Urals, East Siberia), and Venezuela (Orinoco). They represent a future reserve that can only be used when, because of the depletion of the conventional fields, so-called tertiary recovery methods are standard, e.g., hot water injection or steam injection, to extract the oil from the deposits. The prices by then must have exceeded the limit of $ 50/bbl (the oil price in 1992 was ca. $ 20/bbl).

1.1.4.2. Regional Distribution of the Reserves

1.1.4.2.1. Middle East – Arabian (Persian) Gulf

The largest reserves are in the countries of the Middle East and in the Arabian Gulf. On 1st January, 1990, proved reserves of ca. 99×10^9 t were established and probable ones of 19×10^9 t calculated (see Table 1). The first economic oil find in recent times in this region was made in 1908 with the discovery of the Iranian Masjid-i-Sulaiman field. Many subsequent discoveries have been added. At present, Saudi Arabia, with more than 41.5×10^9 t of proved reserves, followed by Iran with 11.75×10^9 t, Kuwait with ca. 13.7×10^9 t, and Iraq with ca. 16.85×10^9 t are leading. The largest deposits in the Middle East include the fields of Burgan in Kuwait, Ghawar, and Safaniya in Saudi Arabia, Kirkuk and Rumaila in Iraq, and the deposits of Gach Saran and Agha Jari in Iran.

Geologically, the oilfields of the Arabian Gulf are situated on the shelf area in front of the pre-Cambrian massif outcropping in the west, and south of the Arabian peninsula in the form of intensively block-folded crystalline. Continental and shallow-water sediments are found deposited between the Cambrian and the Cretaceous systems on the slowly sinking shelf. The shelf is divided by numerous North – South trends that are linked with basement highs. North and east of the shelf, including the Taurus – Zagros – Oman mountains there follows a geosynclinal or plate-edge region. This region also received thick tertiary sediments and during alpidic orogenesis was folded by tangential forces and divided into structures with

a northwest – southeast direction. In accordance with the asymmetric structure of this trough, the large deposits on the Arabian side mainly lie in Jurassic and Cretaceous beds, and the offshore deposits mainly in Cretaceous reservoir rocks. The Persian – Iraqi fields produce in the more deeply settled parts of the trough from Cretaceous and Tertiary horizons. On the Arabian peninsula, anticline-like updomings dominate structurally, whilst in the Persian Gulf salt structures and bending folds, and in the foothills of the Iranian Zagros range anticlinal and overthrust structures can be found. The most recent exploration activities in Saudi Arabia proved deposits with several hundred million tonnes of oil in sandstones of the Paleozoic era. The Permian Khuff, itself a reservoir bed of natural gas deposits, serves here as capping of stratigraphic and structural traps. The oil is of Silurian origin. The Paleozoic era could provide further potential in Saudi Arabia.

1.1.4.2.2. Europe

The petroleum deposits of Europe, apart from the North Sea, are fully developed and, with production falling, are already in the phase of secondary and tertiary recovery methods. If the reserves of all onshore producing countries are combined, proved reserves of ca. 0.7×10^9 t can be established together with exploratory reserves of ca. 0.5×10^9 t. The United Kingdom and Norway possess proved reserves of ca. 5.325×10^9 t from offshore fields, and a further ca. 2.34×10^9 t exploratory reserves are expected. The comparison with the Middle East, however, shows the small importance of the European states as oil-producing countries. Even so, in 1974 the Federal Republic of Germany produced more than 6×10^6 t oil and was able to cover ca. 30 % of indigenous requirements. Of the 823×10^6 t oil reserves originally present, 61×10^6 t proved and probable oil reserves remained after a total production of 225×10^6 t (December 31, 1991). The recovery factor of 35 % of the original reserves means that 537×10^6 t remain unrecoverable. The reserves in Italy and the Netherlands, with developed quantities of ca. 110×10^6 t in each case and prospective reserves of ca. 330×10^6 t in Italy, are – on a worldwide view – of equally low importance as those of Romania, with 190×10^6 t and a prospective reserve of 235×10^6 t. All other countries on the European mainland are globally considered insignificant as producing countries. The oil deposits of northern Germany are bound to sediments of epicontinental floodings which occurred during the Jurassic and Cretaceous periods. The narrow NNW – SSE striking troughs filled with Jurassic deposits are caused by halokinetic movements. The Rhine Valley Graben as a minor oil region dates from the "rifting" (continental drift) related-to young tectonic movements. The European deposits are distributed over the foredeeps of the Pyrenees, the Alps, and the Carpathians, although the deposits in the Aquitaine Basin, the Molasse Basin (Bavaria), the Carpathian Basin, and the Po Basin are not very large. The oil occurrences in Sicily, Spain, and in the Aquitaine Basin of France are linked with Triassic, Jurassic, and Cretaceous carbonates. The intramontane Pannonian Basin and the Paris Basin should be mentioned because of their historic importance for the exploitation of oil in Europe. The Lower-Saxony Basin also is of historic importance, since the deposits of Ölheim (1881) and Wietze (1859) were discovered here almost simultaneously with Colonel Drake's success in the United States.

North Sea. The North Sea has been one of the most attractive exploration regions for the international oil industry since the start of exploration in 1964. All large oil companies, often together with recently founded local partners, have introduced their worldwide know-how into development of this logistically difficult region. Great depths of water, strong currents, and extremely harsh weather conditions require the use of specially developed drilling and production installations. Although the technology used can nowadays be regarded as advanced, the damage to the platforms during construction and operation shows the limits for the prospecting and production of hydrocarbons. The first success in the North Sea was the discovery of the Ekofisk field on the Norwegian Shelf in 1968. Two important successes in the British sector of the North Sea were the discovery of Forties in 1970 and of Brent in 1971. About 17 oil fields are in production in the Norwegian North Sea, and in the British North Sea more than 100 oil and gas fields including numerous small ones. Norway's largest fields are Ekofisk/Eldfisk, Gulfaks, and Statfjord, which have up to now provided ca. 80 % of the Norwegian oil production. In the United Kingdom the Forties, Brent, Magnus, Ninian, Fulmar, and Statfjord (British part) fields provide more than 40 % of the British oil production. The five Danish and seven Dutch offshore fields are negligible compared with those of Norway and the United Kingdom. Geologically, the fields are linked with the large graben that open up from the beginning of the Mesozoic era in conjunction with the rifting of the Atlantic plate. The most important element is the Viking Graben which collapsed between the East Shetland Platform and the Norwegian Vestland Bogen. It runs for a length of ca. 455 km and has a width of ca. 50 km in the south and 180 km in the north approximately on the midline between Norway and the United Kingdom. In addition, there are special basins, some with thick tertiary sediments, to which the oil is bound. The deposits are found in sediments of the Triassic, the Jurassic, the Upper Cretaceous, and the Paleogene periods. The traps are mostly the tilted fault blocks typical of rifting, that are sealed by transgressively overlapping fine-grained Upper Cretaceous sediments. The development of hydrocarbons is limited to the north by the 62nd degree of latitude as a result of Norwegian legislation. Seismic measurements and specifically located wildcats have provided evidence that in the northern North Sea (Tromsø, Haltenbanken) and in the Barents Sea, deposits both of oil and of natural gas can be expected. The time for specific development of these fields will depend on the development of the reserves already developed and also on the oil price. Even today, owing to expensive technology, a price in excess of $ 20/bbl and tax relief by the producing countries is necessary for the continuation of exploration in the North Sea. In 1991, the daily production of all North Sea fields reached 192×10^6 t.

1.1.4.2.3. Commenwealth of Independent States

Industrial oil recovery in the territory of the CIS had already started at Baku in the middle of the last century and reached its first peak around 1900, when North American production was briefly surpassed. After a period of stagnation, a rapid upward development started in the former Soviet Union after World War II with the development of new oil reserves. The proved resources on January 1, 1990, were 13.2×10^9 t, and 14.6×10^9 t of exploratory reserves were expected. Accordingly, the total reserves are more than 200 % higher than those of the United States. Until 1918, almost the whole production came from the Caucasus mountains. In the 1950s the Volga – Urals region and the Timan – Petschora Basin, adjacent to the north, were developed. In addition, the discoveries in the North Caspian Basin (Emba) and in the Mangyschlak trough of Turkmenia developed very rapidly, but have passed their peak. In the 1960s and 1970s, the extended deposits east of the Urals in the West Siberian Basin were discovered. Meanwhile 96 % of the oil developed in West Siberia is produced in the Tjumen province. In the southern provinces of Novosibirsk and Omsk, exploration has given disappointing results. In almost all oil provinces, as a result of technical deficiencies and lack of oil field equipment, production is falling or remaining below expectations. Proved reserves could be mobilized by the use of modern technology, such as the horizontal drilling process in many reservoirs of low permeability. The opening of the CIS to the West leads to the expectation of a

strong involvement of international oil companies which, with their know-how and their modern technology can bring oil exploration and exploitation to a reliable high standard. There are also justified expectations of the development of important new reserves in Turkmenia and East Siberia, where only a small production of oil has been achieved so far. Large oil discoveries in the pre-Caspian Depression promise interesting exploration possibilities. In the recently discovered Thenguise, Astrakhanskoe, and Karatshaganakskoe fields, oil is produced from carbonates and clastics of the Paleozoic era at depths of more than 4000 m below a Permian salt cover. With an area of 500 000 km^2 and a sedimentation thickness of almost 20 000 m, good possibilities also arise here which may increase the number of reservoirs in the CIS substantially. Geologically, the deposits in the Caucasus mountains, the Caspian Sea, Galicia, the Fergana depression, and on Sachalin, etc., are linked above all with Neogen horizons in prealpine depressions and innermontane troughs. The deposits of the Volga – Ural area lie in Paleozoic depressions of the Eastern – European Platform. The main reservoir rocks here are Devonian and Permian reef limestones as well as sandstones of the Carboniferous period. In the large and oil-rich Timan – Pechora Basin, the reservoir systems belong to Upper Devonian sandstones and chalks of the Lower Carboniferous period. Mainly Permian and Mesozoic reservoir horizons are oil-bearing in the deposits of the North Caspian Depression, in Kazakhstan, and Turkmenia. In the deposits of the Western Siberian Platform, the hydrocarbons are assigned to the central part of the Lower or Middle Cretaceous period. In the Molasse Basin of the eastern Ural foreland, oil and gas deposits are linked with Upper Jurassic sandstones and calcarenites.

1.1.4.2.4. Africa

In 1990, the proved and probable oil reserves of Africa were about 11.3×10^9 t, and the exploratory ones ca. 5.0×10^9 t. The resources are concentrated in Libya, Algeria, and Nigeria. There are further deposits of noteworthy size in Egypt, Congo, Angola, Gabon, and Tunisia. The African continent was long considered to have few prospects for hydrocarbons. The breakthrough came in the 1950s with the almost simultaneous discoveries of the first large deposits in Algeria and the Niger delta. The large discoveries in Libya followed in the 1960s. Geologically, the oil deposits of Algeria and the smaller occurrences in West Libya which are not yet producing, are linked to the Paleozoic basin between the Precambrian Massifs of the mid-Sahara and the Atlas range. Fairly large amounts of oil are found in the Neogene basins of the Syrte in Central Libya and in the Niger delta. There are also older oil-producing strata, mostly in the Cretaceous system. At the western edges of the African shield, between several stable cratons, depression fields have been formed, on which marine transgressions deposited thick sediments in the Mesozoic and Tertiary eras. In some cases, between the Permo-Triassic system in Morocco and the Cretaceous system in Gabon, salt deposits occurred that led, possibly in conjunction with the continental drift, to diapirism. The basins not only cover parts of the current mainland but reach far into the Atlantic. The coastal basins range as follows from north to south: Spanish Sahara, Senegal – Mauritania, Ivory Coast, Dahomey, Nigeria, Gabon, Congo, and Angola. In Eastern Africa, of the graben systems which are largely linked to the rifting, only the Red Sea graben with Miocene salt deposits and hydrocarbons below is of importance, as in the Gulf of Suez, which is the only area of East Africa with fairly large reserves.

Libya, with 4.9×10^9 t proved and probable reserves and ca. 1×10^9 t prospective, has the largest oil reserves of Africa. Cumulatively, ca. 2.6×10^9 t oil has been produced in Libya up to now. Geologically, Libya is divided into three large basins: in the west the Murzuk basin, in the central part the Syrte basin, and in the east the Kufra Basin. The oil originates for the greater part from reservoir rocks of the Cretaceous (sandstones) and the Lower Tertiary (reef limestones) systems, but also from the Cambrian and Ordovician systems of the Syrte Basin. Libya's only producing offshore field Bour, with a daily production of ca. 13 000 t (1991), has little importance. The development of hydrocarbons in North Africa began with the discovery of the Zelten (now Nasser) field in 1959. Nasser produces from Lower Eocene limestones of the

Syrte Basin. With original reserves of about 400×10^6 t, it belongs, like Amal and Sarir, with ca. 1.2×10^9 t, to the largest fields of Libya. Libyan oil is low in sulfur and in great demand as a light crude in European refineries.

Nigeria is the second largest producing country in Africa. The proved and probable reserves are indicated as 2.8×10^9 t and the prospective reserves as 1.1×10^9 t oil. The fields are in the Niger Delta Basin that is filled with ca. 12 000 m of clastic rocks of the Tertiary period. In Nigeria, 15 giant oilfields (according to U.S. definition, fields with more than 500×10^6 bbl, ca. 80×10^6 t) have been proved, of which almost half lie offshore.

Algeria, with proved and probable reserves of ca. 1.4×10^9 t, occupies the third position among the producing countries of Africa. The prospective reserves (ca. 240×10^6 t) are quite insignificant. The oilfields lie in the Polignac Basin, near the Libyan border, and in the Ghadames Basin. The fields in Polignac produce from reservoirs in the Carboniferous, Devonian, and Cambro – Ordivician systems. In the Ghadames Basin likewise there are sandstones of the Cambro – Ordivician, that are discordantly overlaid with evaporites.

1.1.4.2.5. North America

Geologically, the North American oil deposits are linked with the large sedimentation region that appeared repeatedly since the Paleozoic era. This basin forms the foredeep to alpine-type mountains in the west (Rocky Mountains) and flattens to the east towards the basement area of the Canadian shield. In the south, this sedimentary basin expands and becomes the thick Tertiary Gulf basin. A lateral arm of the trough zone with Paleozoic rocks follows the southeast edge of the Canadian shield to the mouth of the St. Lawrence river. In accordance with this geological structure, the deposits in the more deeply sunken western sections of the trough appear in Tertiary and Cretaceous horizons, and in the higher-lying eastern marginal areas (midcontinent, eastern states with Appalachians) in sandstones and limestones of the Paleozoic era. The deeply sunken Gulf coast has its main deposits in Cretaceous and Tertiary strata. In the Californian fields, the oil comes from Tertiary and Cretaceous horizons. The new discoveries in Alaska occur mainly in Permo-Triassic sandstones. Other oil discoveries, scarcely developed until now, in the arctic expanse of Canada indicate several very promising basins with possibilities of reservoirs from the Paleozoic era to the Tertiary period.

United States. On January 1, 1990, the United States had available proved reserves of ca. 7.2×10^9 t and prospective reserves of ca. 7.3×10^9 t. Following the producing countries of the Middle East and the CIS, the United States are in the third position. The same ranking applies to the production in the year 1990. The cumulative production of 24.7×10^9 t crude oil was achieved from 597 320 production wells. (The Middle East states produced ca. 26.4×10^9 t from only 7061 wells). The oil resources in the offshore region of Texas, Louisiana, and California were about one quarter of the total reserves. Due to results of exploration in the Gulf of Mexico an increase of the offshore reserves can be anticipated from new discoveries in the deep water region, but this will scarcely lead to compensation for the fall in reserves determined by production. Before Texas, with the coastal strip on the Gulf of Mexico, advanced in 1930 to become the leading petroleum province, the position of the leading producer was occupied by Pennsylvania until the turn of the century, then by California, and later by the midcontinent. On January 1, 1990, the order according to daily production was Texas (ca. 306 179 t), Alaska (281 948 t), Louisiana (171 145 t), California (152 840 t), and Oklahoma (48 900 t).

Canada. Only after World War II did Canada rise to become an important producing country as a result of discoveries in Alberta. On January 1, 1990, the Canadian reserves amounted to ca. 2.1×10^9 t, 7.9×10^9 t of prospective reserves were reported. The daily production of ca. 190 000 t is obtained from 39 159 production wells. The reserves are declining. However, numerous discoveries in arctic regions cannot be developed and therefore cannot be evaluated. More than 80 % of the oil production occurs in Alberta. The hydrocarbons are present in the

foothills of the Rocky Mountains and in the Alberta Plain. The reservoirs for oil, as for natural gas, are present in highly stressed folds, mostly bound to overthrusts, in limestones of the Upper Carboniferous period, more rarely in beds of the Devonian or the Triassic periods. In the Alberta Plain, Paleozoic reef limestones are the reservoir rocks for the oil. Occasionally Cretaceous sandstones are the reservoir rocks, overlaying the Paleozoic discordant.

1.1.4.2.6. Latin America

The most important deposits in Latin America are those of Venezuela and Mexico; Trinidad, Ecuador, Argentina, Peru, Colombia, and Brazil follow some way behind. The main deposits are in the foretroughs of the cordilleras and their branches, and are bound to sediments from the Cretaceous to the Neogene periods. In addition, fairly small coastal basins in Brazil and Argentina are productive. The resource figures have increased due to new discoveries in Venezuela and more recently in Columbia but most of all to the oil accumulations developed in the jungle basins of Ecuador and Peru. Through the development of the Marina – Austral Basin between Tierra del Fuego and the Falkland Islands, the reserves of Argentina have increased considerably. The new reserves are not yet in production because of their geographical position and high gas : oil ratio. The high proportion of prospective reserves in Argentina of ca. 477×10^6 t, as against proved reserves of only ca. 350×10^6 t still points to a good exploration potential. As a result of the large oil deposits in the Bay of Maracaibo and on the Gulf Coast of Mexico, the submarine reserves of Latin America reach 40 % of the total resources. Further offshore deposits are off Trinidad and Brazil.

1.1.4.2.7. Far East

The most important producing regions of the Far East are China, Indonesia, Brunei, and Australia. In addition, oil deposits are known, for example, in Malaysia, Burma, Thailand, Japan, Taiwan, and New Zealand.

China. Only after World War II has China gained importance as a producing country. By the use of modern scientific techniques, the first small fields were discovered in the 1950s. In three regions, groups of fields had been proved by the end of the 1980s that originate from plate-tectonic movements. Up to 1980, 150 fields had been discovered. Of these, merely for reasons of size, only ca. 20 fields are of importance. Even so, the proved reserves have grown to ca. 5.0×10^9 t. The two largest groups of fields, Daqing in East China and Shengli on the Yellow Sea, achieved annual productions of 55.6×10^6 t and 33.5×10^6 t, respectively in 1990; that is ca. 64 % of the Chinese production. In the Daqing field, which was discovered in 1959, between 4000 and 5000 wells distributed over an area of 1200 km^2 are producing from Lower Cretaceous sandstones in very shallow anticlinical deposits. Shengli produces in a group of more than 40 individual structures from Precambrian and Tertiary reservoir beds. Of the numerous sedimentary basins of China, only a few are fully developed. The Tarim Basin (Sinkiang) is expected to be particularly rich in reserves. This extremely large inland basin, of 560 000 km^2, has a sediment thickness of 18 000 m. Since 1983, after intensive geophysical preparation and the sinking of 200 wells – the deepest reaching 6000 m – large quantities of hydrocarbons have been proved in both the North Tarim High and in the center of the Takelmagan Desert. The reserves are estimated at 11×10^9 m^3 oil and almost 8×10^{18} m^3 natural gas. The productive formations are sandstones of the Triassic and Ordovician carbonates. Exploration off the coasts of China is operated as joint ventures with international oil companies. Starting from onshore discoveries, in the Bohai Sea, east of Beijing (Peking), a series of fields has been developed whose potential is estimated to be more than 150×10^6 t crude oil. In the occurrences discovered in the South China Sea, no important reserves are yet known. The crude oil of the Bohai Basin originated from tertiary sediments of various structural types, including stratigraphic traps.

Other Areas. Important new discoveries have been made in recent years, especially in the submarine areas of Indonesia, Brunei, and South Australia (Tasman Strait). Of the devel-

oped reserves of the Far East, offshore deposits could account for almost one third. The most important reservoir horizons are in the Tertiary system; Mesozoic and Paleozoic formations are secondary possibilities. Wide shelf areas off the northwest Australian Coast as well as on the Indonesian and Chinese Shelves are regarded as favorable for future exploration.

1.2. Natural Gas

Natural gas has gained considerable importance in the past decades. Enormous gas reservoirs in Siberia, the Middle East, Algeria, and in Europe, connected by pipeline systems with the consumer countries, contribute substantially to the energy supply. The deposits in North America are, for environmental reasons, an important energy source for households and industry because of the fuel's cleanliness. Natural gas deposits in tropical regions are at present still underprivileged, since this gas can only be used in the industrial countries after liquefaction and transportation by ship. This is economically possible only if the price level offers an appropriate margin for this treatment of natural gas. The composition of natural gas is extraordinarily diverse (see also → Natural Gas, Chap. 1.1.). Aside from the so-called "dry", i.e., pure methane gas, "wet" gases with varying proportions of higher hydrocarbons occur. Inert constituents, such as nitrogen and carbon dioxide, reduce the calorific value. Sulfur and mercury are pollutants when the natural gas is used and must be removed from it (→ Natural Gas, Chap. 2.3.1., → Natural Gas, Chap. 2.3.2.). In connection with this, the elementary sulfur removed from the gas secures its own economically significant market value. The proportions of helium in the nitrogen-rich natural gases are, in general, small and only in a few cases do they allow extraction for economic utilization (→ Noble Gases, → Noble Gases, Chap. 4.2.1.). The natural gases arising in the limestones and dolomites of the Northwest German Zechstein contain up to 20 vol % hydrogen sulfide. The natural gas in the French Lacq field contains 15 vol % H_2S; while 63 % and 88 % are known from reservoirs in Wyoming in the United States and in Alberta, Canada (→ Hydrogen Sulfide, Chap. 4.2.). Since the gases containing hydrogen sulfide usually occur in contact with gypsum or anhydrite beds, formation of hydrogen sulfide is ascribed to bacterial reduction of calcium sulfate. Natural gas deposits with considerable percentages of heavy hydrocarbons are known as condensate deposits. While wet natural gases and condensates mainly lie adjacent to oil deposits or are associated with them, dry natural gases are usually found in separate gas provinces. This already follows from the fact that the majority of dry natural gases can be derived from the kerogen III arising from terrestrial plants. Other dry, natural gases are formed in parts of deep basins where pressure and temperature have exceeded the threshold value at which crude oils form. A distinction is made between *associated gas,* which is closely connected with crude oil, and *nonassociated or natural gas,* which is separately generated, predominantly from kerogen III. The associated gas dissolved in the crude oil is released during production by pressure reduction. If the crude oil is supersaturated, then part of the gas migrates upwards and usually forms a gas cap, which under certain conditions, can be exploited separately.

The *nonassociated gas* stands for deposits of dry natural gases that have been formed from kerogen III. This is methane gas (CH_4) being produced from beds of the Upper Carboniferous, the Rotliegendes, and the Zechstein systems in the British North sea, the Netherlands, Germany, and in Poland. It is beyond doubt that this gas originates from the solid coal seams below the reservoirs or from vegetable residues dispersed in sediments of the lower part of the Upper Carboniferous system. The "petroleum gas", as a byproduct of oil production, plays only a subsidiary role in energy supply – apart from exceptions such as Ekofisk. Large amounts of this gas are used in the production plants or, usually after compression, fed to regional gas supply systems. In low-pressure reservoirs, the petroleum gas is returned to the reservoir to raise the pressure which consequently reduces the production costs by a longer-lasting eruptive phase. In the large producing countries, for example on the Arabian Gulf and in North Africa, enormous quantities of petroleum gas are flared, thus being both wasteful and environmentally polluting.

Since ca. 1980, the theory of the abiogenic origin of the hydrocarbons in the ground has gained interest again. Gold postulates that the

vast quantities of bound (oxidized) carbon, e.g., in carbonates, cannot originate from the atmosphere but escape from the mantel of the Earth. The presence of helium, that originates from the radioactive decay of certain minerals, is also quoted by GOLD as evidence, as are methane inclusions in diamonds, in kimberlite, or the high methane content in Lake Kivu, which lies over a rift fault. The theory is based on the finding of a methane atmosphere for the outer planets and their moons. Evidence for methane of abiological origin was to be provided in the mid-1980s by a deep borehole in the so-called Siljan Ring in Sweden. From this enormous meteorite crater, oil and gas traces were reported from water wells and flammable gas was detected from lakes and pools. Gravimetric measurements showed an anomaly that was interpreted as a zone of good porosity in the granite, created by finely divided hair cracks and clefts due to impact by the meteorite. The borehole sunk to 6080 m from July 1986 to January 1987 and did not establish proof of abiogenic gas. German scientists intend to investigate the problem of the so-called mantle gas in collaboration with the natural gas industry and the federal ministry responsible.

As with abiogenic hydrocarbons from the Earth's mantle, the question of the origin of the nitrogen in natural gases, involving the theory of the inclusion of air in the Earth's crust, is still being discussed. More probable theories suggest an enrichment process of nitrogen as a result of fractional differentiation during gas migration, formation of nitrogen by the action of anaerobic bacteria during oil generation in the source rock, and its release from vegetable materials during coalification. For the origin of the Northwest German nitrogen enrichments, the possibilities under discussion include a relatively late split off from the Upper Carboniferous coal seams and a concentration by fractional differentiation on the migration paths.

1.2.1. Origin and Deposit Formation

Natural gases in the narrower sense, i.e., the combustible hydrocarbons, are often closely related to the crude oils, both genetically and above all with regard to deposit formation (see Sections 1.1.1 and 1.1.2). Petroleum and natural gas frequently occur in the same geological level of a region. On the other hand, coal and petroleum occurrences in the same level of a region are almost entirely mutually exclusive. Dry natural gas as a derivative of coalification – both in regions with thick coal seams as well as in those with dispersely distributed coaly material – is also often found directly adjacent to petroleum regions, e.g., in the Emsland and the Wiehengebirgsvorland of Northwest Germany. The majority of natural gas occurrences in the world is linked with oil provinces. Associated natural gases, often in connection with an economically uninteresting oil seam of low thickness (e.g., the enormous gas deposits in the north of the West Siberian Platform), predominate. As a result of fractional migration effects, accumulations of dry gas deposits can also occur.

Gas formation in petroleum source rocks proceeds in different ways. In the diagenesis phase, occurring in immature source rocks, bacterial methane is generated from kerogen III. At $> 60\,^{\circ}C$, the splitting-off of wet gas from kerogen I and II begins – in addition to oil formation – which continues to the lower end of the oil window at $150\,^{\circ}C$. At higher temperature dry thermal gas is increasingly formed. The natural gas deposits of the Rotliegendes and of the Zechstein in the natural gas belt between the south of the British North Sea and Poland owe their formation, as already mentioned, to the solid coal deposits in the underlying Upper Carboniferous system. The coal-bearing beds were probably subjected, already at the end of the Carboniferous period, to an early coalification which was so low that 30 % of the volatiles remained in the coal. As a result of the further sinking of the coal seams by thick Cretaceous and Tertiary overlying strata, the temperature required for natural gas formation rose again and the coalification process continued with release of further methane. The majority of the gas deposits arising between England and Poland, including the Groningen deposit, owe their formation to such processes.

Theoretically, a further cause for the formation of natural gas is its genesis from oil shales. As in the technical recovery of gas from oil shales, including the Kukersit shales of Estonia (→ Oil Shale, Chap. 7.1.), natural pyrolysis

processes at temperatures far above 200 °C are possible, by which natural gas could have been formed from oil shales.

1.2.2. Natural Gas Occurrences and Their Reserves

The importance of the natural gas producing countries is reflected in their present reserves. The amounts produced annually have increased as a result of the consolidation of the international pipeline network. In addition, interest in natural gas has increased because it is the cleanest of the fossil fuels; it is much less polluting than coal or oil. Large reserves also justify the high investment for the treatment and pipeline transport of the natural gas (→ Natural Gas, Chap. 4.1.). The production quantities reported are not a measure of the natural gas potential available in the producing countries, which follows from the growth of the reserves. This is evident on comparing the United States and the CIS In 1989, production in the United States was 500×10^9 m^3, and that of the CIS 739×10^9 m^3. On January 1, 1990, the proved and probable reserves of the United States were ca. 8.4×10^{12} m^3 and those of the CIS ca. 45×10^{12} m^3. To these there must be added exploratory reserves ca. 11×10^{12} m^3 for the United States and ca. 35×10^{12} m^3 for the CIS The disproportion between production and reserves in the CIS originates in missing pipeline connections, line losses, and also marketing problems. Other large natural gas producers are Canada, the Netherlands, Iran, Venezuela, the United Kingdom, Romania, Mexico, China, and Germany. The large natural gas potentials in the countries of the Arabian Gulf, in Nigeria, and in Indonesia suffer from the distance of the markets, since a basic requirement for transportation from remote countries to the trade centers is the liquefaction of the natural gas. Because of the relatively small capacity of the liquid gas tankers and the large distances to be covered, the economic use of liquid gas is often at or below the break-even point. The natural gas resources of the world – proved and probable – on January 1, 1990, were ca. 127.0×10^{12} m^3, and the prospective another ca. 121×10^{12} m^3. The CIS has developed its leading position through the enormous new discoveries, above all in Western Siberia, and is followed by the Middle East, which also has a very powerful growth to record. The raising of the proved gas reserves in these two large districts originates not only in new discoveries but partly in the extension or higher evaluation of deposits already known and the strengthened inclusion of petroleum gases, particularly in the Middle East and Venezuela. While Africa and North America show a declining trend for the proved reserves, Western Europe has improved its position in the international gas sector by further new discoveries in the North Sea.

1.2.3. Regional Distribution of the Reserves

A breakdown of natural gas production and resources according to region is given in Table 2.

1.2.3.1. Commonwealth of Independent States

The largest reserves in the world, at 45×10^{12} m^3, are those of the CIS The occurrences are widely spread and in some cases combined with petroleum deposits.

The first great gas boom was in the 1950s with the development of the fields of Shebelinka in the Dnieper – Donetz Trough and Gazli in Central Asia, each with primary resources of $450-500\times10^9$ m^3. The discoveries in the second half of the 1960s, some of which were enormous, established the present position of the CIS in the natural gas sector. Important deposits mentioned are those of Krasny – Kholm (Orenburg) in the Volga – Urals district, where ca. 750×10^9 m^3 of gas have been discovered, and the Vuktyl and Layavozh deposits in the Petchora Basin, linked with beds of the same age and each with ca. 500×10^9 m^3 of gas. In Turkmenia, the Malai field with ca. 340×10^9 m^3, is one of the giants. Probably the largest natural gas province in the world is in the north of the Western Siberian platform. The gas occurring here in sandstones of the Cretaceous system (predominantly Cenomanian), in part several hundred meters thick, consists of almost pure (97 – 99 %) methane. The structural traps are extended anticlines and mound-like highs. About 220 fields have been developed in this area up to now.

Table 2. Natural gas production and resources up to December 31, 1989 (assembled from various international data)

	Cumulative production, 10^9 m^3	Resources	
		Proven and probable, 10^9 m^3	Prospective, 10^9 m^3
North America	23 436	11 000	18 700
Latin America	1 734	7 000	10 600
Middle East	1 629	42 000	26 700
Africa	924	7 400	9 300
Far East	2 306	9 800	13 700
Europe	4 970	5 800	7 200
CIS	10 150	44 000	34 800
World	45 149	127 000	121 000

This producing province is the most important for the future export of gas to Europe. Its most extensive deposits include the Urengoy field, the largest deposit proved so far with ca. 6×10^{12} m^3 of initial gas reserves, and also the large deposits of Jubileyny (ca. 2×10^{12} m^3), Taz (ca. 1.15×10^{12} m^3), Medvezhye (ca. 1.05 $\times10^{12}$ m^3), and Yamburg (ca. 850×10^9 m^3) among others. At least a further ten fields of this region have each reported primarily more than 100×10^9 m^3 of recoverable gas reserves. Two new discoveries in the Arctic Ocean deserve attention. In 1987 in the Barents Sea, not far from the Norwegian border, the Shtowmanowskaja field with an estimated reserve of $3-4\times10^{12}$ m^3 was discovered, and in 1988 in the Kara Sea, the Russanowskaja field with 6×10^{12} m^3. Both fields together are credited with 15 % of the future production provided that the production and transportation to Nowaja Semlja is possible under arctic conditions.

1.2.3.2. Middle East

Even if not so dominant as in the case of crude oil, the areas on the Arabian Gulf, with proved natural gas reserves of ca. 68×10^{12} m^3 play an important role in the possibility of future exports. However, a considerable fraction of these quantities is trapped in gas caps or is dissolved petroleum gas linked with the large oilfields of this area and is therefore dependent on their production. The gas cap of the Pazanan oilfield in Iran alone contains recoverable quantities of ca. 1.4×10^{12} m^3 of gas. With the recent discovery of enormous gas accumulations in the Permian Khuff formation, very large dry gas deposits have also been proved for the Middle East. The Kangan field in Iran is said to contain 4×10^{12} m^3 of resources. The deposits available in the Permian formation are sealed above by triadic salt beds. There are further deposits of this type, not hitherto exploited, in Qatar. Iran also is involved in the northern part of the Northwest Dome (North Field) – with $2.8-3.4\ \times10^{12}$ m^3 a "super giant" – which belongs to the Permian Khuff. Notable natural gas reserves are also known in Saudi Arabia and the Emirates.

1.2.3.3. North America

Despite higher quantities produced, the known North American gas reserves have risen again. The reserves of 9×10^{12} m^3 in the mid 1970s have risen to ca. 11×10^{12} m^3 proved and probable. Of these, 8.4×10^{12} m^3 in the mid 1980s were assigned to the United States alone, the traditional land of natural gas. Its large-scale industrial use started here even before the turn of the century. In addition to this, exploratory reserves of almost 20×10^{12} m^3 can be anticipated in North America. The largest deposits in the United States are in Texas, Oklahoma (particularly in the deep Anadarco Basin), Kansas, and New Mexico with the fields of Hogoton (initial reserves ca. 1.1×10^{12} m^3) and Panhandle (primary resources ca. 870×10^9 m^3), which are already in part greatly depleted. A large fraction of the resources are in the Rocky Mountain Province with 1.25×10^{12} m^3. The natural gas here is predominantly bound to Permian carbonate rocks, but is also found in sandstones, arkoses, and weathered granite zones. Other deposits, such as the Blanco Basin field in New

Mexico and Rio Vista in California, occur in Cretaceous sandstones and Lower Paleozoic carbonate rocks (Pucket field, Texas).

The gas accumulations of the American Gulf Coast are mainly associated with oil deposits or are found in separate reservoirs over the oil in Tertiary sandstones. The recoverable gas contents of these latter isolated deposits are only between 100 and 300×10^9 m^3.

The North American gas deposits, especially those on the Gulf Coast, are frequently characterized by a relatively high nitrogen content.

1.2.3.4. Africa

The proximity of Algeria and Libya to the industrial countries of Europe favors the export of natural gas to Europe. Altogether, supply contracts for more than 80×10^9 m^3/a have been closed, of which 12×10^9 m^3 are conveyed by pipeline to Italy and the remainder, after liquefaction, by tanker mainly to Germany and a further part to the United States. In addition to the gas reserves of the oil-producing countries Libya and Algeria, that mostly occur as dissolved gas, there are dry gas deposits, particularly in Algeria. The largest African field, Hassi R'Mel in the Algerian Sahara, discovered in 1956, has been in production for years. The gas that contains 86 % methane occurs in triadic sandstones in the area of an anticline. The original resources were assessed as ca. 1×10^{12} m^3, but are probably more than double that amount.

1.2.3.5. Western Europe

The Western European deposits were of only local significance until the discovery of the large Groningen gas field in 1959/1960 and the subsequent discoveries in the North Sea. The small Western European gas production comes mainly from the French field, Lacq, in the Pyrenean foredeep, with primary reserves of ca. 200 $\times10^9$ m^3, as well as from deposits in Northwest Germany and the Netherlands where they are mostly bound to Zechstein dolomites and from Tertiary reservoir rocks in the German Alpine approaches. There are smaller production areas in the inner-alpine Vienna basin, in the Po plain, and off the Adriatic coast of Italy. The Austrian and Italian reservoirs occur mainly in Tertiary horizons. As a result of the development of the gas deposit of Groningen in the 250 m thick Rotliegendes sands, with initial reserves of ca. 1.9×10^{12} m^3 and a methane content of ca. 82 vol %, the exploration boom for inferred natural gas accumulations of the Rotliegendes in the North Sea and for the neighboring region of Germany started from 1963/1964. In the North Sea a distinction can be made between a dry gas province in the southern North Sea with deposits off the eastern English and Dutch coasts, and the gas deposits of the central and northern North Sea. The latter are mostly associated with oil deposits and linked with the Dan formation but, most of all to sandstones of the Paleogene system.

The deposits in the *southern North Sea* generally occur, as in the Groningen field, in the sandstones of the Rotliegendes. The methane gas, like most of the accumulations in Northwest Germany, is attributed to coalification processes in the underlying seam-bearing Upper Carboniferous system.

The natural gas reservoirs *further to the north* could be of similar origin, in the broadest sense, with the oil deposits proved there. These are partly gas cap gases and partly gas accumulations in separate reservoir horizons above oil deposits, or above economically uninteresting oil seams.

On January 1, 1992, ca. 4400×10^9 m^3 natural gas had been discovered and developed in the North Sea. Of this, ca. 1200×10^9 m^3 was assigned to the United Kingdom, ca. 2700×10^9 m^3 to Norway, ca. 350×10^9 m^3 to the Netherlands, and ca. 110×10^9 m^3 to Denmark. The results of drilling from the German North Sea give no indication of major natural gas deposits comparable with those of the neighboring sectors. Only one minor natural gas deposit in the extreme part of the German North Sea with reserves of ca. 10×10^9 m^3 is under development. Production, in the North Sea, mainly from British gas fields, increased from ca. 50×10^9 m^3 in 1985 to 98×10^9 m^3 in 1991.

The largest known gas deposits in the North Sea include the following fields: Frigg (Paleocene sandstone, ca. 400×10^9 m^3 resources); Leman (Rotliegend sands, ca. 300×10^9 m^3 reserves); Indefatigable (Rotliegend sands, ca. 140×10^9 m^3); Viking (Rotliegend sands, ca.

140×10^9 m^3); L-10/11 (Rotliegend sands, ca. $100-140\times10^9$ m^3); K 13 (Rotliegend sands, ca. $100-140\times10^9$ m^3); Hewett (Triassic sands, ca. 110×10^9 m^3); Troll (Middle/Upper Jurassic, ca. 1600×10^9 m^3).

With continuous exploration on the Norwegian Shelf (Arctic Ocean and Barents Sea) further large natural gas discoveries can be expected.

2. Reservoir Engineering

2.1. Characterization of Oil and Gas Reservoirs

As described in Chapter 1, oil and gas reservoirs are accumulations of hydrocarbons that are stored in porous or fissured strata of the Earth's outer crust and contain a commercially valuable quantity of oil or gas. A precondition for storage in the sedimentary rocks is a continuous cavity, in the form of pores or fissures, that permits transport of the fluids into pressure sinks (wells). Since these sedimentary strata can be found at various depths, it is important that the rock matrix takes on the high rock compression stress without much deformation so that when pore pressure is released, the pore fluids can easily flow to the pressure sink, i.e., the well. If large deformations were to occur in the rock, the flow paths in the neighborhood of the well could close upon pressure release thus resulting in the virtual sealing of the reservoir.

2.1.1. Reservoir Rock

The most important reservoir-forming sedimentary rocks are described in Section 1.1.2.2. Since the reservoir rock rarely has a monomineralic character, its mineral composition and the internal surfaces resulting from it are very important, both for the storage capacity of the rock and for the transmissibility of the fluids stored within it. The crystal structure and specific internal surface of the rock-forming minerals determine the types of porosity of a reservoir rock.

In principle, cavities are found in a mineral structure along the cleavage planes of crystals (*intercrystalline pore space*), within the layer lattice of crystals (*intracrystalline pore space*), and, on a larger scale, along the boundary surfaces of particles (*interparticulate pore space*) or within the particle at mineral boundaries or growth defects (*intraparticulate pore space*). Hydrocarbons are stored mainly in the interparticulate pore space of clastic sediments or the *fissured* pore space of chemical sediments (limestone, dolomite). Fissures form in a rock as a result of deformation when the shear strength is exceeded.

Figure 7 shows the typical composition of a porous clastic sediment (detrital rock). The rock body consists of sediment particles (grain) that are mainly composed of mineral components quartz, feldspar, and mica; of bioclasts; or oolites. In most cases the rock particles are cemented together by calcites, dolomites, silicates, or clay minerals. In the interparticulate pore space so formed, pore fillings of clay minerals, quartz, and mica can lower the available porosity.

Figure 7. Composition of a detritral rock [72]
a) Grain (texture: sand granules 1/16 – 2 mm diameter; silt 1/256 – 1/16 mm diameter); b) Pore fillings (texture: sand granules 1/16 mm diameter; silt 1/16 – 1/256 mm diameter; clay $<$ 1/256 mm); c) Cement; d) Fluid

2.1.1.1. Porosity

Porosity ϕ defines the ratio of the pore volume V_p of a reservoir rock to the bulk volume V_b of the rock:

$$\phi=\frac{V_\mathrm{p}}{V_\mathrm{b}}$$

According to this definition, the porosity also includes the volume of isolated pores (*dead pores*).

If all interconnected elements of the pore volume are taken into account, the *effective porosity*

Figure 8. Grain-size distribution and porosity
A) Low porosity; B) High porosity

is obtained. This is an indicator of the effective storage volume of a rock. The sum of effective ϕ_{eff} and dead ϕ_{d} porosities gives the total porosity:

$$\phi_{\mathrm{eff}} + \phi_{\mathrm{d}} = \phi$$

For geometrical or hydrodynamical reasons, not all pores are available for convective mass transport. A fixed portion of the cavity volume can be regarded as *dead-end* pore volume.

The porosity depends essentially on four characteristics of the sedimentary rock:

1) Particle shape
2) Degree of cementation
3) Particle size distribution
4) Particle arrangement

The influence of particle shape and degree of cementation is evident from Figure 7. In general, the more edged the particles, the greater is the interparticulate component of the pore space. The available porosity decreases with increasing cement component. The most important influencing factors, however, are the particle size distribution and the particle arrangement in the rock structure.

Figure 8 A shows a wide distribution of particle diameters which leads to a large reduction in porosity, since the interparticulate pore space formed by the coarse fractions is filled up by the fine components. On the other hand, a narrow particle size distribution (Fig. 8 B) results in a high porosity. In the lower half of the figure, the cumulative particle size distribution is also shown. Usually the steeper the cumulative curve, the greater is the porosity of the rock.

Three special cases of particle arrangements and the corresponding porosities are shown in Figure 9. In the cubic, space-centered sphere packing (Fig. 9 A), in which the particle midpoints form the corners of a cube, the interparticulate pore volume is exactly 47.6 % of the total volume. In this case each particle has six points of contact with the neighboring particles. In the hexagonal arrangement of particles (Fig. 9 B), the spherical particles of the upper lattice plane are displaced by half the particle diameter relative to the lower lattice plane. In this arrangement, the number of contacts rises from six to eight and the porosity decreases to 39.5 %. If in the second lattice plane of the packing, the row of spheres is displaced not only in the x-direction by $d/2$, but also in the y-direction perpendicular to it, by $d/2$, the densest packing of spheres is obtained (C). Here in the rhombohedral arrangement the particles of the upper lattice plane are placed exactly in the holes of the lower plane and accordingly each particle has twelve neighbors and the porosity is only 25.9 %. The porosity of a

natural packing of cemented sedimentary grains usually falls between the limiting values of 39.5 and 25.9 %.

Figure 9. Packing and porosity [73]
A) Space-centered, cubic sphere packing (number of contacts = 6, $\phi = 47.6\,\%$); B) Hexagonal packing (number of contacts = 8, $\phi = 39.5\,\%$); C) Densest packing of spheres (rhombohedral) (number of contacts = 12, $\phi = 25.9\,\%$)

2.1.1.2. Pore Configuration Models

Although, at first glance, the shape of the pores or fissures of a sedimentary rock has very little to do with regular geometric forms, cylindrical capillaries or parallel plates are regarded as geometrically similar to the pores and fissures and are chosen as models for calculating the pore space properties. These very simple geometries are unable, however, to reproduce the irregular variation of the pore or fissure cross section or of the tortuosity of flow path, which are important characteristics of the pore configuration.

In Figure 10, the commonest types of pore configuration models, up to the most advanced representation (fractal network model), are shown. The *capillary bundle model* (Fig. 10 A) is the most frequently applied pore configuration model, mainly used for calculating the pore radius distribution, the saturation with fluids, and the oil displacement process. A particular drawback of this model is that a transverse flow between the capillaries is not possible. A pore configuration model for fissured reservoir rocks derived from the plate model is the *brickstone model* (B), in which the individual blocks symbolize the porous matrix and the gaps between them, the fissures. Here mass transfer between matrix and fissure is possible. The *intersphere network model* (C) is used particularly for determining the phase distribution in the pore space and the capillary forces. With the *cascade network model* (D), dead-end pore effects, turbulence effects, and mixing phenomena can be investigated.

According to the principle of self-similarity of geometric forms in nature, relations are traceable as far as between the crystal forms in the microcosmos and the geological outfits (morphology) of the Earth's surface. In connection with this, the fractal dimension is a scale-up factor between the characteristic dimensions and the image scales. If the spherical shape (circular shape in Fig. 10 E) is chosen as the characteristic elementary shape of the rock structure and of the pore space, a fractal network for matrix and pore configuration can be developed, whose specific internal surface and volume fraction are calculable and correlatable with other physically measurable quantities such as electrical conductivity and permeability.

An example of the use of pore configuration models for calculating pore space properties is given here, based on the determination of the pore radius distribution by the mercury injection method. If the total pore space V_p is assumed to be represented by a bundle of capillaries of various diameters, then on injection of a nonwetting liquid phase (i.e., mercury) the individual sizes of capillary are filled stepwise (ΔV) as the pressure is raised. Since the injection pressure for mercury p_c is inversely proportional to the radius of the capillaries, the proportions by volume $\Delta V/V_p$ of the individual capillary radii can be estimated from the mercury injection curve

$$p_c = \frac{2\sigma_{Hg}\cos\theta_{Hg}}{r}$$

where σ_{Hg} is the surface tension of mercury and θ the wetting angle of contact.

In order to reconcile this measurement with actual pore space configurations, it must be taken into account that each pore has at least two characteristic dimensions – the pore entrance and the pore widening. The characteristic cross-section determined by the mercury injection method corresponds to the pore entrance radius.

2.1.1.3. Compressibility of the Pore Space

The compressibility c of a substance is the change, with external pressure, of its volume

Figure 10. Pore configuration models [74]
A) Capillary bundle model; B) Brickstone model; C) Intersphere network model; D) Cascade network model; E) Fractal network model
White color means pore space.

relative to its initial volume. For a solid the compressibility is negligibly small. A porous medium which is built up of individual particles can, however, change its particle arrangement under pressure and, therefore, is said to have considerable compressibility. The deformability is discussed for the different forms of packing of spherical particles in Section 2.1.1.1. According to the studies of Geertsma [75], the pore volume compressibility c_f depends on the type of pore configuration (porosity of the medium) and the effective pressure which is the difference of external pressure p_e and internal pore pressure p_i.

$$c_f = (-)\,\frac{1}{V_p}\,\frac{\partial V_p}{\partial\,(p_e - p_i)}$$

Figure 11 shows that the pore volume change reacts with increasing sensitivity to an increase in the external pressure with decreasing porosity. The porosity of sedimentary rock under in situ conditions (i.e., under the influence of the overburden pressure of the sediments) can, therefore, be up to 20 % smaller than the porosity determined in the laboratory [77].

Figure 11. Compressibility of the pore volume [76]

2.1.2. Physical Properties of the Pore Saturating Fluids

Gas, oil, and water are the relevant pore saturating fluids, whose physical properties must be known as a function of the pressure, the reservoir temperature, and the fluid's composition. The material properties of these multicomponent systems can only be predicted for the gas state at low pressure with acceptable accuracy and without an extensive experimental data base.

For liquids and phase mixtures, estimates of the material properties are obtained in accordance with the theorem of corresponding states by normalizing to conditions at the critical point. The state variables, pressure, and temperature, are normalized by introducing the reduced pressure p_r and temperature T_r (→ Estimation of Physical Properties, Chap. 2.2.).

$$p_r = \frac{p}{p_c} \quad T_r = \frac{T}{T_c}$$

Mixtures with complex structure can be described by means of pseudocritical pressure and temperature that are calculated from the molar fractions of the individual components and the corresponding individual pseudocritical quantities. These simple correlations yield satisfactory results only when the individual components have similar critical pressures and critical volumes.

In all other cases three-parameter thermodynamic functions of state are used to improve the accuracy of prediction. These calculation methods are based on the attempt to produce a functional relationship between the critical material properties of a component and the molecular interactions. Nevertheless, no known equation of state is able to determine all properties of hydrocarbon mixtures equally satisfactorily.

For determining the contents of a reservoir and for calculations of recovery and flow processes, the most important physical parameters are the density, compressibility, and viscosity of the fluids. In the following, the methods of calculation applied in practice will be considered without showing the full physical background. The reader is referred to the references [77], [78] given at the end of this article.

2.1.2.1. Density

The density of a *gas* ϱ_g can be calculated directly from the equation of state for real gases

$$\varrho_g = \frac{M_r p}{z R T}$$

where M_r is the molecular mass, p the pressure, z the real gas factor, R the gas constant, and T the temperature.

The reduced temperature and the reduced pressure serve as adjustment parameters for the real gas factor z. For gas mixtures, instead of the molecular mass M_r the mean molecular mass of the mixture is used together with the real gas factor for the mixture.

For direct calculation of *liquid densities,* this simple form of the equation is inadequate. Because of the higher packing density of the molecules in the liquid allowances must be made for the inherent volume of the molecules and for molecular interactions.

If the critical densities or the densities of the individual components under standard conditions are known, the density of the mixture ϱ_f can be determined from the molar fractions according to the rule of additive properties

$$\varrho_f = \frac{\sum_1^n z_j M_{rj}}{\sum_1^n \frac{z_j M_{rj}}{\varrho_{0j}}}$$

For reservoir calculations, the so- called *formation volume factor B* is usually used instead of density for converting gas and liquid volumes to reservoir or standard conditions. The formation volume factor is the ratio of the volume under reservoir conditions to the volume under standard conditions.

$$B = \frac{\text{Volume at pressure } p \text{ and temperature } T}{\text{Volume at standard conditions } (p_0, T_0)}$$

where the standard conditions for gases are: $p_0 = 0.1013$ MPa and T_0 273.15 K. For liquids $p_0 = 0.1013$ MPa and $T_0 = 293.15$ K holds.

In the United States, 60 °F, corresponding to 288.65 K, is used as standard temperature. The *formation volume factor for gas* B_g can be calculated directly from the real gas equation:

$$B_g = \frac{z T p_0}{p T_0}$$

From a double-logarithmic plot of the formation volume factor versus pressure, a linear curve is obtained as long as the influence of the real gas factor at elevated pressure is not noticeable (Fig. 12).

Figure 13 shows the formation volume factor for oil, B_o, as a function of pressure at constant temperature.

Figure 12. Formation volume factor for gas

Figure 13. Formation volume factor for oil [78]

For a gas-undersaturated oil, the formation volume factor B_o at first increases with decreasing pressure as a result of the liquid-phase expansion of the oil and reaches its maximum value at the bubble point pressure (p_b). The greater the gradient of the branch of the curve between the initial reservoir pressure (p_i) and the bubble point pressure, the more compressible is the liquid. When the pressure falls below the bubble point pressure, the volume of the oil and with it the formation volume factor decreases rapidly. The final value of 1 is not reached, since the thermal shrinkage of the oil from reservoir-temperature to standard-temperature condition occurs at a final pressure of 0.1 MPa. To describe the volume behavior of a two-phase mixture of gas and oil, the two formation volume factors can be added to obtain the two-phase formation volume factor B_t, taking the gas – oil ratio (R_s) into account.

$$B_t = B_o + B_g\,(R_{si} - R_s)$$

where R_{si} is the initial gas – oil ratio.

In Figure 13 the upper part of the curve is identical to the two-phase formation volume factor B_t. The formation volume factor for water B_w, which is shown in Figure 14, does not show a decrease through shrinkage resulting from degassing below the bubble point pressure (p_b). Instead, it rises further as a result of volume expansion on pressure release. This is due to the relatively low dissolved gas volume in water (ca. 1 m^3 gas/m^3) compared with oil (10 – 50 m^3 gas/m^3).

Figure 14. Formation volume factor for water [78]

2.1.2.2. Compressibility

The isothermal compressibility of the pore fluids is given by:

$$c = -\frac{1}{v}\frac{\partial V}{\partial p_T}$$

The pore fluids differ clearly in their compressibility behavior. While gases in the pressure range 0.1 – 100 MPa are extraordinarily compressible ($c = 10^{-5} - 10^{-8}\ \mathrm{Pa}^{-1}$), oils have a moderate to low compressibility ($c = 10^{-8} - 10^{-10}\ \mathrm{Pa}^{-1}$) depending on their dissolved gas content, and water has a compressibility of ca. $10^{-10}\ \mathrm{Pa}^{-1}$. The last figure is of the same order as the compressibility of the rock pore volume. In calculating the compressibility of real substances, the normalized thermodynamic functions of state, pressure, and temperature can be used.

For a *gas mixture* under real conditions, the compressibility equation reduced to normalized-conditions is:

$$c_g = \frac{c_{\mathrm{pr}}}{p_{\mathrm{pc}}} = \frac{1}{p_{\mathrm{pc}}}\left[\frac{1}{p_{\mathrm{pr}}} - \frac{1}{z}\frac{\partial z}{\partial p_{\mathrm{pr}}}\right]$$

Here, instead of the critical data for a single gas, pseudocritical values (p_{pc} and T_{pc}) are used as normalizing quantities.

$$p_{\mathrm{pr}} = \frac{p}{p_{\mathrm{pc}}} \quad p_{\mathrm{pc}} = \sum_1^n y_j p_{c_j}$$

$$T_{\mathrm{pr}} = \frac{T}{T_{\mathrm{pc}}} \quad T_{\mathrm{pc}} = \sum_1^n y_j T_{c_j}$$

where p_{pr} is the pseudoreduced pressure, T_{pr} the pseudoreduced temperature, and y_j the molar fractions of the individual components.

For an ideal gas, whose z factor is 1, the gas compressibility is therefore inversely proportional to its pressure. For liquids, whose critical z factor is 0.27 (most higher molecular mass hydrocarbons satisfy this condition), the compressibility can be determined from normalized pressure – temperature graph [78].

2.1.2.3. Viscosity

According to Newton, the dynamic viscosity μ is the proportionality factor between the shearing stress in the flow direction and the resulting shearing rate change perpendicular to the flow direction. Gas, oil, and water largely behave as Newtonian substances. For the viscosity of *gases* at low pressure and constant temperature, the product of the free path, mean velocity and the density of the gas molecules is a measure of internal friction. At low pressure, only the Brownian motion velocity of the molecules is relevant for this energy transfer and the viscosity of gases therefore increases with the square root of temperature. Only at elevated pressure does a reduction of the internal friction and, therefore, the viscosity, appear with gases and liquids with increasing temperature.

For *gas mixtures* the mixing rule definition for n components applies.

$$\mu_g = \frac{\sum_1^n y_j \mu_{g_j} M_j^{0.5}}{\sum_1^n y_j M_j^{0.5}}$$

To allow for the influence of pressure and temperature on the viscosity of a real gas, the normalized representations of the reduced pressure and temperature can again be employed.

The pressure and temperature dependence of the viscosity of reservoir oils is shown in Figures 15 and 16, respectively. Above the bubble point pressure p_b, the viscosity linearly increases with the reservoir pressure. Below the bubble point pressure, the oil viscosity falls steeply with increasing pressure or gas content.

Figure 15. Viscosity of oil as a function of pressure [78]

The temperature dependence of the viscosity of oil is characterized by an exponential function, so that in a semilogarithmic plot versus

the reciprocal of the absolute temperature (see Fig. 16) a straight line is obtained. The slope of this straight line is greater the higher the oil's content of heavy components. For the dependence of the viscosity of water on the temperature the same mathematical relationships apply. In addition, the viscosity of water increases with increasing salt content [79].

a) Heavy crude oil; b) Medium crude oil

2.1.3. Reserves

A detailed discussion of worldwide resources of oil and gas is given in Sections 1.1.4 and 1.2.3, respectively.

Resources mean the total volume of hydrocarbon stored in reservoirs. With oil, gas, or condensate reservoirs, the initial volume of the pore contents, the so- called original oil in place (OOIP) or original gas in place (OGIP), is the first quantity used for evaluating a resource. Since for physical, technological, and economic reasons the resources are not completely recoverable, a second concept is necessary for characterizing the profitability of a discovery: the reserves. *Reserves* mean those quantities of hydrocarbons that at a given time are proved on the basis of sufficient geological and reservoir engineering information and can, in future, be produced with currently available methods of recovery and applicable economic conditions. Reduced to a simple formula,

$$\text{Reserves} = \text{Resources} \times \text{Recovery factor}$$

The recovery factors for oil reservoirs, apart from a few exceptions, are between 20 and 45 % of the contents. For gas reservoirs, the recovery factor can be up to 85 %. The degree of certainty in the determination of the reserves increases with increasing development of a reservoir. According to a classification of reserves made by the Committee of the World Petroleum Congress, "proven reserves" are spoken of when the probability of proof exceeds 90 %, and "unproven reserves" when that probability is between 10 and 90 % [80]. The unproven reserves are split by a median value of 50 % into probable and possible reserves. The remainder are the speculative, so far undiscovered, possibly recoverable reserves.

Volumetric Determination of the Reservoir Contents. At the start of development of an oil or gas reservoir, usually only the contours of the reservoir are known; apart from test analyses data, no adequate production and pressure trends are available. The content of a reservoir can then be surveyed only by volumetric methods. The contents related to standard conditions are calculated from the following formulae:

$$\text{OOIP} = \frac{V_\text{b}\,\phi\,(1-S_\text{wi})}{B_\text{oi}}$$

$$\text{OGIP} = \frac{V_\text{b}\,\phi\,(1-S_\text{wi})}{B_\text{gi}}$$

where OOIP denotes original oil in place, OGIP denotes original gas in place, and S_wi is the initial water saturation.

The bulk volume of the reservoir V_b is determined from a geological model of the reservoir. In this procedure the nonproductive regions of the strata must also be taken into account such as clayey interlayers or lenses, water-bearing belts, and the distinction between gas-, oil- and water-bearing zones (gas – oil – water contacts) when delimiting the net rock volume from the gross rock volume. In the evaluation of borehole measurements, so- called cut-off values for porosity, saturation, clay content, and permeability are introduced to differentiate between pay zone and nonproductive thickness and to determine the pay zone thickness (Fig. 17). The black areas correspond to the porous, hydrocarbon-bearing formation intervals that are included in the net layer thickness.

For displaying the geological models, various mapping methods are chosen. For example, in Figure 18, the structural map of a reservoir is

Figure 17. Net pays from well logging [81]

represented by subsurface contour lines (that is in feed). For determining the net rock volume of a reservoir, the reservoir body can be imagined to be divided into a large number of slices of equal thickness. Each of these slices can be represented by a geometrically similar body such as a truncated cone, truncated pyramid, or other, irregular shapes, allowing its volume to be calculated. A more elegant method is the graphical evaluation of the subsurface contour planes. In this method the areas of the contour line map determined by planimeter for the upper and lower boundary of the reservoir are plotted against the relative depth in a system of cartesian coordinates [77].

Furthermore, if the lower and upper boundaries of the reservoir contents – the gas – oil and water – oil contacts, respectively – are taken into account, the rock volume can be determined directly from the area – depth graph by means of millimeter paper or planimetry. These computed or graphically-determined rock volumes are inserted into the formulae for calculating the OOIP and OGIP. In low-permeability reservoirs bearing formation water, the transition zone from the completely water saturated zone to the oil

bearing zone, containing irreducible water, is an uncertainty factor in the oil or gas resource calculation. The transition region is characterized by the capillary pressure curve.

Figure 18. Isomap representation of reservoirs/regular contours [82]

2.2. Flow Processes in Porous Media

The original state of a crude oil or natural gas reservoir is characterized by the thermodynamic equilibrium of the hydrocarbon phases and the capillary equilibrium of the wetting and nonwetting phases, which in turn depends on the prevailing temperature, pore space pressure, and rock properties. Not only the composition but also the properties of the oil, gas, and water phase show a remarkable "memory" for the early history of the formation of the deposit. For example, oils that lack in certain alkanes can be recognized as intermediate products of biological degradation from an original sapropellitic material. Light oils which have been exposed to oxidation as a result of tectonic postsedimentary processes, might have been converted into medium-heavy oils, but they still retain the chemical features (fingerprints) of their origins.

The initial distribution of the phases in the pore space is governed by the equilibrium between interfacial forces and viscous forces during the migration process. If a volatile oil enters a porous rock which is saturated with salt water and flushes the pore space over extended periods then the resulting initial water saturation in the deposit is normally greater than the adsorbed water saturation (i.e., the layer of water retained by physical adhesion to the interior surfaces of the rock). If, in contrast, the migrating oil is composed of heavier hydrocarbon fractions, it displaces the pore water almost down to the level of the absorbed water saturation. After a reservoir has been filled, the materials are in dynamic rather than static equilibrium. Diffusion and convection can influence the material equilibrium and the distribution of the phases in the deposit.

2.2.1. Single-Phase Flow

If a fluid with little or no compressibility (water, oil) is flowing in an infinitely large reservoir system towards a pressure sink (well) then – after a transient phase – a steady-state condition is reached between the quantity removed from the well and the quantity flowing in from the deposit. Under these conditions, the pressure changes only as a function of space, but not of time. However, during the transient state before the steady-state equilibrium is reached the pressure also changes with time.

2.2.1.1. Steady-State Flow – Darcy's Equation

In the laminar flow regime – i.e., in a homogeneously porous medium with a Reynolds number < 1 – Darcy's law holds; a single well in an infinitely large reservoir radial flow geometry can be assumed

$$\frac{q}{2\pi r h} = \boldsymbol{v} = -\frac{k}{\mu}\frac{\partial p}{\partial r} \tag{2.1}$$

where q is the flow rate, r the radius, h the thickness of the porous layer, $\boldsymbol{v}$ the apparent velocity, k the permeability of the rock, μ the dynamic viscosity, and p the pressure. Integration of Equation (2.1) between the well radius r_{w} and the radius r_{e} of the area drained by the well gives the following for steady-state flow:

Boundary conditions: p_{e} at r_{e}; p_{wf} at r_{w} are constant with time

$$q_{\mathrm{w}} = \frac{2\pi h k}{B\mu}\frac{(p_{\mathrm{e}} - p_{\mathrm{wf}})}{\ln r_{\mathrm{e}}/r_{\mathrm{w}}} \tag{2.2}$$

where B is the formation volume factor of the fluid.

However, for a *compressible medium* (gas) the volume flow is not constant along the direction of flow. If Darcy's formula is still to be applied it is necessary to convert the flow rate to some mean pressure p_m between the system's input and output pressures [77]. The average flow rate can be converted to the required flow conditions in the well by using the equation of state for ideal gases.

Boundary conditions for linear geometry: p_e at $x = l$; p_{wf} at $x = 0$, where x denotes the distance from the well.

$$p_m = \frac{p_e + p_{wf}}{2}$$

$$q_m = \frac{Ak}{\mu}\frac{(p_e - p_{wf})}{l}$$

$$q_w\, p_{wf} = q_m\, p_m = -\frac{Ak}{\mu}\frac{(p_e^2 - p_{wf}^2)}{2l}$$

$$q_w = -\frac{Ak}{B\mu}\frac{(p_e^2 - p_{wf}^2)}{2p_{wf}l}$$

2.2.1.2. Transient Single-Phase Flow

Consider a space element in the form of a cylindrical capillary of length Δx and cross-sectional area A (Fig. 19). A mass flow $(\varrho \boldsymbol{v}_x)_x A$ is injected at the inlet end and the mass flow $(\varrho \boldsymbol{v}_x)_{x+\Delta x} A$ emerges at the outlet point at a distance x.

Figure 19. Material balance in a cylindrical capillary of length Δx and cross-sectional area A

Under transient flow conditions, the difference between these two mass flows corresponds to the mass stored in the volume element ΔV. The material balance must be maintained because of the principle of conservation of mass.

$$A\,\Delta t \quad ((\varrho \boldsymbol{v}_x)_x - (\varrho \boldsymbol{v}_x)_{x+\Delta x}) = \text{Mass stored}$$

(Mass in − Mass out)

divided by $A\,\Delta x\,\Delta t$

$$\lim_{\substack{\Delta x \to 0 \\ \Delta t \to 0}} \frac{(\varrho \boldsymbol{v}_x)_{x+\Delta x} - (\varrho \boldsymbol{v}_x)}{\Delta x} = -\frac{\Delta \varrho_{\Delta t}}{\Delta t}$$

$$\frac{\partial\,(\varrho \boldsymbol{v}_x)}{\partial x} + \frac{\partial \varrho}{\partial t} = 0$$

The differential equation for the continuity law is obtained from the difference equation assuming small increments of time and space. The nabla operator and the porosity in the storage volume ΔV are introduced so that this equation can be applied to a porous medium and extended to three-dimensional flow conditions. For horizontal flow of a medium of low compressibility, the extended continuity equation becomes:

$$\nabla\,(\varrho \boldsymbol{v}) + \frac{\partial\,(\phi\,\varrho)}{\partial t} = 0 \tag{2.4}$$

In one dimension:

$$\boldsymbol{v}_x = -\frac{k}{\mu}\frac{\partial p}{\partial x}$$

$$-\frac{\partial}{\partial x}\left(\varrho \cdot \frac{k}{\mu}\frac{\partial p}{\partial x}\right) + \frac{\partial\,(\phi\,\varrho)}{\partial t} = 0 \tag{2.5}$$

$$\frac{k}{\mu}\left[\frac{\partial \varrho}{\partial x}\frac{\partial p}{\partial x} + \varrho\frac{\partial^2 \mathrm{p}}{\partial x^2}\right] = \Phi\,\frac{\partial \varrho}{\partial t}$$

where k/μ is the transmissibility of the pore fluid for a given porous medium.

As an initial condition it was assumed that the transmissibility k/μ and the porosity ϕ are constant throughout the pore space system. The compressibility equation

$$c = -\frac{1}{\varrho}\frac{\partial \varrho}{\partial p}$$

for a fluid of low compressibility is introduced and used to replace the change in density ϱ by the change in pressure p.

$$\frac{k\,\varrho}{\mu}\left[c\left(\frac{\partial p}{\partial x}\right)^2 + \frac{\partial^2 p}{\partial x^2}\right] = \varrho c \Phi\,\frac{\partial p}{\partial t}$$

Both sides are multiplied by the product $\mu/k\varrho$. The flow rate, at some distance from the well, is only in the range of a few centimeters per hour

so the pressure gradient p/x and the square of the pressure gradient are very small in comparison with the other variables in Equation (2.5). This term can therefore be neglected.

This then gives Equation (2.6) which is similar in form to the diffusivity equation, and is referred to as the pressure propagation or hydraulic conductivity equation for the one-dimensional case.

$$\frac{\partial^2 p}{\partial x^2} = \frac{\phi \mu c}{k} \frac{\partial p}{\partial t} \tag{2.6}$$

Equation (2.5) can also be solved for other initial conditions. If the density of the fluid phase is defined by a mass law, e.g., the gas law for ideal gases, then the following form of the hydraulic conductivity equation is obtained

$$\frac{\partial^2 \left(p^2\right)}{\partial x^2} = 2 \frac{\phi \mu}{k} \frac{\partial p}{\partial t} \tag{2.7}$$

These equations can also be represented in three-dimensional form. To solve Equations (2.6) and (2.7) it is necessary to adapt the flow geometry and boundary conditions to match the situation in the deposit. For a cylindrical coordinate system Equation (2.8) is obtained.

$$\frac{\partial^2 p}{\partial r^2} + \frac{1}{r} \frac{\partial p}{\partial r} = \frac{\phi \mu c}{k} \frac{\partial p}{\partial t} \tag{2.8}$$

With a linear pressure sink as the well, and for infinite extension of the reservoir, i.e., $r_e = \infty$, the Boltzmann transformation can be used for solving Equation (2.8).

The following boundary conditions apply:

$t=0$	$r=r_w$	$p=p_i$
	$r=r_e$	$p=p_i$
$t=t_1$	$r=r_w$	$p=p_{wf}$
	$r=r_e$	$p=p_i$

The result of the Boltzmann transformation is the exponential integral equation:

$$p_{wf} = p_i + \frac{q\mu}{4\pi h k} E_i \left(\frac{-\phi \mu c_t r^2}{4kt} \right) \tag{2.9}$$

where the symbol E_i denotes exponential integral and p_{wf} the flowing pressure at the bottom of the well.

In an infinitely large homogeneous reservoir system with a line source as the well, the flowing pressure at any point can be calculated from Equation (2.9) as a function of the radius r and the time t. The natural logarithm can be used in place of the exponential integral provided the argument of the exponential integral is significantly smaller than the limiting value of 0.01 [83].

$$p_{wf} = p_i + \frac{q\mu}{4\pi h k} \ln \frac{\gamma \phi \mu c_t r_w^2}{4kt} \tag{2.10}$$

where γ denotes the Euler constant.

To reconstruct the situation in a deposit, the deposit's hydraulic system must be transformed back to its original state. This can be done by, for example, closing off an operating well. The pressure in the well will then gradually build up again until it reaches the original reservoir pressure, assuming that the deposit is comparable to an infinitely large reservoir system (influence of aquifers). The shut-in of the well is simulated mathematically by superimposing a negative flow rate q on the radial flow system. Combination of the two equations for the influx into the well and the out flow from the well gives an equation for the shut-in pressure p_{ws} of the following form:

$$p_{ws} = p_i - \frac{q\mu}{4\pi h k} \ln \frac{t_p + \Delta t}{\Delta t} \tag{2.11}$$

where $t_f = t_p$ denotes the flow duration and Δt the shut-in time [84]. This equation has been used to extrapolate the initial reservoir pressure p_i from the graphical presentation of the shut-in pressure plotted against the logarithm of the time ratio ($\frac{t_p + \Delta t}{\Delta t} = 1$ (Fig. 20).

Figure 20. Shut-in pressure p_{WS} versus logarithmic time ratio $\frac{t_p + \Delta t}{\Delta t}$ for extrapolation of initial reservoir pressure p_i [83]

For an infinitely large reservoir the initial pressure in the well will be reconstituted after an infinite shut-in time $\frac{t_p + \Delta t}{\Delta t} = 1$. The gradient of the straight line m corresponds to the coefficient in Equation (2.11) in front of the logarithmic function. As the flow rate is normally determined in a measuring tank above ground, it has to be transferred to the state in the deposit. This is done by incorporating the formation volume factor B in the defining equation for m.

$$m = \frac{q \mu B}{4 \pi h k}$$

From the gradient m the permeability capacity $k \cdot h$ can be calculated for the reservoir system.

$$kh = \frac{q \mu B}{4 \pi m}$$

In addition to this simple radial model with the selected initial and boundary conditions many methods exist for finding solutions for specific reservoir conditions, which can be applied to individual well and reservoir problems. Individual solutions have therefore been found for the differential equations to the following conditions; finite reservoir extension, near wellbore effects, fractured reservoirs, stratified reservoirs, and partial penetration and particular direction of the well in the producing formation.

2.2.2. Multiphase Flow

2.2.2.1. Capillary Pressure and Saturation

If there is more than one phase in the pore space system of a reservoir rock then the distribution of the phases is determined by the interfacial tensions between the fluids and the solid phase. The equilibrium of forces between two liquid phases (oil and water) and a solid phase is shown in Figure 21.

Figure 21. Equilibrium of forces between two liquid phases (water and oil) and the solid phase [77]
σ_{so} = interfacial tension solid – oil; σ_{sw} = interfacial tension solid – water; σ_{wo} interfacial tension water – oil

The wetting angle θ is a measure of the wettability of the solid phase by the oil and water phases. A value of 0° for θ represents an ideally water wet solid, whereas 180° defines a completely oil wet surface. The distribution of the phases for a pore cross section therefore can be idealized as follows:

- Water, as the most strongly wetting phase, is positioned directly against the surface of the rock
- Gas, which is the least wetting, is positioned in the center of the pore duct
- The oil phase is distributed between them (Fig. 22)

Figure 22. Idealized distribution of oil, water, and gas phase in a pore cross section
a) Water; b) Gas; c) Oil; d) Rock

Due to the adhesive forces the pressure in the wetting phase (water) is lower than in the nonwetting phase (oil). The difference between these two pressures is the capillary pressure p_c where

$$p_c = p_o - p_w$$

Capillary pressure curves (see Fig. 23) are of fundamental importance for the mobility of the phases in multiphase flow. They determine the irreducible, and, therefore, fixed saturation of the wetting phase at infinite capillary pressure and characterize the capillary ascent of the water table at the boundary of the oil – water zones. The capillary pressure can be directly transferred into

elevation by use of the capillary/gravity force equilibrium.

$$\frac{2\sigma_{\mathrm{ow}}\cos\theta}{r} = (\varrho_{\mathrm{w}} - \delta_{\mathrm{o}})_{gh}$$

where σ_{ow} denotes the interfacial tension between oil and water phase, r the equivalent hydraulic radius of the porous system, ϱ_{w} the density of water, δ_{o} the density of oil, g the gravitational constant, and h the elevation above the water table.

Figure 23. Capillary pressure versus wetting fluid saturation [85]
a) Low permeability; b) High permeability

For the same capillary pressure, a higher water saturation is found in a pore space system of lower permeability (a) than in a highly permeable one (b). If it is assumed that water represents the wetting phase this means a reinforced capillary imbibition of water from zones of high permeability into low permeability and therefore an improved displacement of oil from the pores of lower permeability.

2.2.2.2. Relative Permeabilities

The mobilities of the individual phases in multiphase flow in a porous medium depend on the wettability of the rock, on the interfacial tension between the fluids, and on their viscosities. A new flow coefficient, which is introduced into the phase flow equation as the *relative permeability,* is needed to describe the different mobilities of the phases in the medium as a function of their fractional saturation. Relative permeability k_{r} is defined as the ratio of the effective permeability of a phase (k_{w}, k_{o}, k_{g}) in the presence of one or more adjacent phases to a reference permeability. The absolute rock permeability according to Darcy, or the permeability to water at 100 % water saturation, or the permeability to oil for irreducible water saturation can be used as the reference permeability. The relative permeabilities for a binary oil – water system for a more strongly water-wet and a more strongly oil-wet rock are shown in Figure 24. If the saturation of the wetting phase S_{w} is plotted on the abscissa then the curves are displaced to the right with increasing water wettability. On the other hand, the final value for the relative permeability of the water phase increases if the water wettability decreases.

Figure 24. Relative permeabilities for a binary oil – water system [86]
A) Water-wet rock; B) Oil-wet rock

This type of representation can only be used for two-phase permeabilities; for a three-phase system STONE [87] has proposed a paired representation of the water – oil and gas – oil relative permeabilities.

Apart from this, a ternary diagram is the only possible way of representing the relative permeabilities of a three-phase system.

The flow equations for a two-phase system can therefore be represented while taking account of the functions of the relative permeabilities and the capillary pressure.

Oil:

$$\nabla\left[-\frac{k_{\mathrm{ro}}k\,\varrho_{\mathrm{o}}}{\mu_{\mathrm{o}}}\nabla\boldsymbol{\Phi}_{\mathrm{o}}\right]=\boldsymbol{\Phi}\frac{\partial S_{\mathrm{w}}}{\partial p_{\mathrm{c}}}\left(\frac{\partial\boldsymbol{\Phi}_{\mathrm{o}}}{\partial t}-\frac{\partial\boldsymbol{\Phi}_{\mathrm{w}}}{\partial t}\right)$$

Water:

$$\nabla\left[-\frac{k_{\mathrm{rw}}k\,\varrho_{\mathrm{w}}}{\mu_{\mathrm{w}}}\nabla\boldsymbol{\Phi}_{\mathrm{w}}\right]=\phi\frac{\partial S_{\mathrm{w}}}{\partial p_{\mathrm{c}}}\left(\frac{\partial\Phi_{\mathrm{o}}}{\partial t}-\frac{\partial\Phi_{\mathrm{w}}}{\partial t}\right)$$

where $\boldsymbol{\Phi}$ is the flow potential:

$$\boldsymbol{\Phi}\frac{1}{\varrho}\,(p+\varrho g z)$$

and k_{ro} and k_{rw} denote the relative permeabilities of oil and water, respectively.

Depending on the boundary conditions, this system of partial differential equations, can, in general, only be solved numerically.

Figure 25. Binary diagram for a gas – oil mixture (each phase consisting of one component) [77]
A = bubble point pressure (pressure depletion at room temperature); A′ = initial reservoir pressure; C = critical point

2.2.3. Drive Mechanisms and Recovery Efficiency

The energy reservoir for the flow of oil, gas, and water in a porous medium consists of the compression energy of the aquifer volume surrounding the deposit; the mechanical energy of the gas liberation process; the influence of gravity; and the capillary pressure effect.

As shown in Section 2.2, the initial pressure in a deposit is mainly hydrostatic. The ratio of the initial pressure to the saturation pressure of the oil – gas mixture characterizes the individual steps of the oil recovery process and the drive mechanism. Figure 25 shows a simplified binary diagram for a mixture of gas and oil, each phase consisting of one component.

In this $p-T$ diagram the oil recovery process is considered isothermal. If the initial reservoir pressure p_{i} lies above the bubble point pressure p_{b} the deposit is termed a gas undersaturated oil deposit. When the pressure is released the volume expansion drive alone is initially effective. When the pressure falls below the bubble point pressure, this is supplemented by the mechanical effect of the gas liberation process. If the bubble point pressure and initial reservoir pressure are equal then the deposit is termed a gas-saturated oil deposit. If the initial reservoir pressure lies below the bubble point pressure then the expansion effect of a gas cap can provide an additional drive mechanism. From Figure 25 it can also be seen that no oil deposits exist to the right of the critical point C and that the gas reservoir or con-densate phase type then begins. The influence of the different drive mechanisms is best calculated from a material balance (see Section 2.3.1). The physical and mathematical treatment of these material balances assumes closed systems in which removal of fluid results in a reduction of pressure. If, however, the removal of fluid is replenished by an aquifer feed, or by water or gas injection then the system pressure remains essentially unchanged. A pressure change in the system also changes the properties of the phases in a way which is disadvantageous to the oil recovery process (see Section 2.1.2); measures which maintain the pressure are, therefore, favorable. *Water drive* is by far the most effective drive mechanism; it can be introduced by artificial flooding measures in locations where

water cannot be fed from natural sources (i.e., inadequate aquifer size or inadequate energy replenishment due to low aquifer permeability). The oil recovery process by natural aquifer expansion and by the other drive mechanisms mentioned rate as *primary extraction processes.* On the other hand, replenishment of the reservoir energy by water or gas injection is one of the *secondary extraction processes*.

Figure 26. Oil recovery efficiency as a function of pressure for various drive mechanisms [88]
a) Depletion drive; b) External gas drive (small gas cap); c) External gas drive (large gas cap); d) Water drive

The *recovery efficiency* of a deposit is given by the percentage of the cumulative production of the quantity of hydrocarbon originally present. The performance of extraction and the recovery efficiency are determined largely by the geological factors of the deposit and the physics of the oil recovery process. The physical approach to oil recovery processes presupposes a microscopic dimension, and the geological approach a macroscopic one; the recovery factor must, therefore, include microscopic and macroscopic parameters. The total recovery factor or recovery efficiency E_{R} is the product of the microscopic recovery factor E_{D}, the areal recovery factor E_{A}, and the vertical recovery factor (flood invasion efficiency) E_{I}. Figure 26 shows that the recovery efficiencies lie between 20 % and 40 % of the oil present, depending on the characteristic drive mechanisms and oil viscosities. In gas reservoirs the recovery efficiency lies between 80 and 90 % of the gas present. This is attributable to the high mobility of the gas and the favorable form of the volume expansion drive.

Figure 27. A) Saturation distribution along flooding section (direction x); B) Fractional flow for water along flooding section

2.2.3.1. Microscopic Recovery Factor

BUCKLEY, LEVERETT, and WELGE [89–91] have developed the theory of the displacement of a fluid by a second, immiscible fluid in a homogeneous medium. This microscopic process determines which fluid exhibits the stronger wetting properties towards the porous medium and which has the greater mobility. The displacement process in the pore space is not as perfect as the displacement of a fluid by a piston in a machine; this is because a mobile residual phase saturation of the displaced fluid (oil) remains after the displacement front has passed. Continued flooding can reduce this mobile residual phase saturation down to an irreducible, fixed percentage. Through a linear flooding process it is pos-

sible to determine the saturation distribution S along the flooding section, i.e., in direction x (Fig. 27).

Figure 28. Mass balance for an infinitely small volume unit at the saturation boundary between oil and water

At the inlet cross section the water saturation is only slightly smaller than the difference of 1 minus the physical residual oil saturation S_{or}. Up to the flooding front, the water saturation decreases to a value S_{wf} (front saturation), depending on the mobilities of the phases. The difference between the ultimate water saturation $(1-S_{\mathrm{or}})$ and the actual water saturation at any section is defined by the profile f, the saturation of mobile oil. The front is characterized by a step change in the water saturation down to the *irreducible water saturation* S_{wi}. The proportions of the flowing phases change along this saturation profile and can be expressed by the fractional flow f of one of the two flowing phases, as it is shown for different times t_1 and t_2 in Figure 27 B.

$$f_{\mathrm{w}}=\frac{q_{\mathrm{w}}}{q_{\mathrm{o}}+q_{\mathrm{w}}}=\frac{1}{1+M^{-1}}$$

$$M=\frac{\lambda_{\mathrm{w}}}{\lambda_{\mathrm{o}}}=\frac{k_{\mathrm{rw}}\,\mu_{\mathrm{o}}}{k_{\mathrm{ro}}\,\mu_{\mathrm{w}}}$$

The fractional flow for water is a function of the mobility ratio M, i.e., the mobility of water $k_{\mathrm{w}}/\mu_{\mathrm{w}}$ as the displacing phase to the mobility of the oil $k_{\mathrm{o}}/\mu_{\mathrm{o}}$ as the displaced medium. At the front the fractional flow of water falls to zero, as only the mobile oil phase can flow ahead of the front. By using a continuity approach in the porous medium the velocity has been determined at which the front or the saturation profile moves through a pore continuum [90]. If an infinitely small volume unit is considered at the boundary between oil and water then the difference between input and output water flow volume in the time unit Δt must be equal to the change in saturation in the space element $A\,\Delta x$ (see Fig. 28).

$$\Delta t\,(q\,f_{\mathrm{w}_1}-q\,f_{\mathrm{w}_2})=A\,\Delta x\phi\,(\mathrm{S}_{\mathrm{w}_1}-S_{\mathrm{w}_2})$$

This finite difference equation can then be transformed into a differential equation which gives the velocity of propagation of a point on the saturation profile.

$$\lim_{\substack{\Delta x\to 0\\ \Delta t\to 0}} q\Delta f_{\mathrm{w}}\,u\Delta t=A\Delta x\,\phi\Delta S_{\mathrm{w}}$$

$$\frac{\partial x}{\partial t}=\frac{q}{A\,\phi}\,\frac{\partial f_{\mathrm{w}}}{\partial S_{\mathrm{w}}}$$

Integration between the limits x and 0 and the times t and 0 gives the equation for determining position x which has reached some arbitrary saturation value at the time t after injection of a certain volume of water W_{i}.

$$x=\frac{W_{\mathrm{i}}}{A\,\phi}\,\frac{\partial f_{\mathrm{w}}}{\partial S_{\mathrm{w}}}$$

$$W_{\mathrm{i}}=\int_0^t q\mathrm{d}t$$

If, instead of some arbitrary saturation, the intention is to characterize the saturation at the front, and hence the front velocity v_{f}, then Figure 29 illustrates the graphic method for determining the front saturation.

The saturation at the displacement front S_{wf} is defined by the point where the tangent to the fractional flow curve from its origin intersects the curve itself. An extension of this tangent until it intersects the fractional flow value 1, characterizes the average water saturation $\bar{S}_{\mathrm{wbt}}$ as the front breaks through at the end of the flooding section. The difference $1-S_{\mathrm{or}}-\bar{S}_{\mathrm{wbt}}$ provides a measure for the residual oil which can be mobilized. In practice this mobilizable residual oil can only be extracted after an infinitely long flooding time. The greater the mobility of the displaced phase in comparison with the displacing phase the more rapidly the residual oil saturation reaches a quasi steady-state final condition S_{or}. This physical residual oil saturation

serves as a measure for establishing the microscopic oil recovery factor E_{D}.

$$E_{\mathrm{D}} = \frac{S_{\mathrm{oi}} - S_{\mathrm{or}}}{S_{\mathrm{oi}}} = 1 - \frac{S_{\mathrm{or}}}{S_{\mathrm{oi}}}$$

Figure 29. Fractional flow curve for water, definition of the front saturation S_{wf} and break through saturation $\bar{S}_{\mathrm{wbt}}$ according to Welge [92]

2.2.3.2. Areal Recovery Factor

Consider a homogeneous deposit with no vertical stratification and a concentric arrangement of the peripheral production wells at a distance r from an injection well. Here the areal oil recovery factor E_{A}, i.e., the ratio between swept area A_{S} and the total area A, would be equal to 1 by the time the flooding front has reached the peripheral production wells.

For a five-point well pattern as shown in Figure 30 a considerable proportion of the area A remains unswept when the flooding front reaches the four peripheral production wells. The areal oil recovery factor which can be achieved before breakthrough of the flooding front depends on the mobility ratio of the front and the arrangement of the wells.

Figure 30. Concentric arrangement of four peripheral production with respect to one injection well, 5-point pattern

In a homogeneous producing formation the well spacing initially plays no part. However, as the capacity of the producing formation to accept the injection medium (water) depends on permeability, the well spacing cannot be set at any arbitrary distance. There is little point in optimizing the well spacing on the basis of a homogeneous deposit model, as in practice more complex deposit formations are often found.

2.2.3.3. Vertical Recovery Factor or Flood Invasion Efficiency

If the oil producing formation were to have no vertical subdivisions then the overall oil recovery factor from this deposit would be the product of the microscopic and areal oil recovery factors. However, the conditions under which the sediments were deposited have normally led to a vertical, facially subdivided stratification, with the result that the vertical recovery factor also has to be taken into account when determining the overall oil recovery.

If water is invading into a stratified producing formation from an aquifer or an injection well the strata fill in the order of their permeabilities. The most permeable layer is flooded first.

Dykstra and Parsons [93] have developed a simple theory for determining the vertical recovery factor in a stratified producing formation. For

this purpose they have further simplified the microscopic displacement process as described by BUCKLEY and LEVERETT and have assumed that no mobile residual oil remains behind the front. However, unlike BUCKLEY and LEVERETT, they have taken into account the fact that the velocity of the displacement front depends on the mobility ratio of the phases and on the position of the displacement front along the flooding section. The higher the mobility of the displacing phase the more rapidly the flooding front extends toward the end of the flooding section. The flooding velocity at the inlet corresponds to the effective Darcy flow velocity of the oil phase (see Fig. 31).

Figure 31. Relative velocity of flooding front as function of fractional distance for different mobilities of displacing phase [94]
a) $M = 0.1$; b) $M = 0.2$; c) $M = 0.5$; d) $M = 1$; e) $M = 2$; f) $M = 5$; g) $M = 10$

The flood invasion efficiency E_{I} is given by integration of the water saturation profile in Figure 32 using the following formula

$$E_{\mathrm{I}} = \frac{\sum_{1}^{i} h_j + \sum_{i+1}^{n} \frac{x_j}{l} h_j}{\sum_{1}^{n} h_j}$$

The position of the flooding front at time t in the incompletely swept strata $j = i + 1$, relative to the layer i in which the water has just broken through, is determined by the equation

$$\frac{x_j}{l} = \frac{\left[M^2 + \frac{k_j}{k_{\mathrm{i}}}\left(1 - M^2\right)\right]^{0.5}}{1 - M} - \frac{M}{1 - M}$$

where x_j/l is the position of the flooding front.

The following formula applies to the time until breakthrough t_i

$$t_i = -\frac{\phi l^2 (M+1)\, \mu_w}{2 k_{wi} \Delta p}$$

With the aid of these three equations the vertical oil recovery factor can be determined at any given time. The product of the three factors gives the overall recovery efficiency E_{R}:

$$E_{\mathrm{D}} = E_{\mathrm{D}}\, E_{\mathrm{A}}\, E_{\mathrm{I}}$$

Figure 32. Cross section of a layered reservoir; position of flood front in the individual layers at a certain time level t [94]

2.3. Modeling of Reservoir and Production Performance

An effective reservoir characterization comprises a description of the reservoir's geological boundaries, the petrophysical properties of the rock, and the material properties of the contents. Its aim is to calculate the production behavior and plan measures to optimize production from the reservoir. The calculation methods used are the basis for predictions of future production performance and are a strategic instrument of reservoir management. All methods of prediction are based on the physical fundamentals of the recovery process and the flow properties of the fluids in a geologically complex reservoir body. The credibility and reliability of these prediction methods depend on how closely the calculation techniques model the reality of the recovery process and the reservoir. This accuracy of the model must be checked by a *model validation* before use. Once the model is chosen it must be adjusted to the production history of the reservoir (*model calibration*). The better the model is calibrated, the more reliable the prediction.

The following models for describing the reservoir behavior, with increasing complexity of process description and/or reservoir characterization, can be distinguished:

1) Tank models (material balances)
2) Combined tank – flow model (Tarner prediction method)
3) Multiphase flow models (reservoir simulation)

2.3.1. Material Balances Method

The tank model is the simplest form of reconstruction of the reservoir contents. It is based on the conservation of mass and an equation of state [88]. All forms of material balance use the following approach:

$$\text{Original contents} - \text{Quantity produced}$$

$$= \text{Quantity remaining}$$

In order to set up a material balance the following assumptions must be made:

1) The reservoir is considered as an energetic unit
2) The material properties and the pressure can be described by mean values representative of the reservoir
3) The material laws for the pore contents can be determined with sufficient accuracy

Material Balance for a Gas-Undersaturated Oil Reservoir Without Aquifer Influence This material balance is presented as an example.

Initial State:

1) The initial pressure p_i exceeds the bubble point pressure p_b
2) The reservoir contents consist of the volume of gas-undersaturated oil NB_{oi} and the volume of initial water V_{wi}

$$V_{pi} = \frac{N B_{oi}}{1 - S_{wi}}$$

$$V_{wi} = V_{pi} S_{wi}$$

(for explanation of terms see the abbreviations list at the beginning of this article).

State Above the Bubble Point Pressure p_b:

1) The actual pressure exceeds the bubble point pressure p_b but is lower than p_i.
2) The oil volume $N_p B_o$ is produced. The volume lost is replaced by the expansion of the rock matrix, the residual oil, and the initial water.

$$V_p = V_{pi} \left[1 - c_f \left(p_i - p\right)\right]$$

$$V_w = V_{wi} \left[1 + c_w \left(p_i - p\right)\right]$$

$$\left(N - N_p\right) B_o = \text{Residual oil}$$

(for explanation of terms see the abbreviations list at the beginning of this article).

State Below the Bubble Point Pressure p_b:

1) The reservoir pressure p is less than the bubble point pressure p_b.
2) Aside from the volume expansion of oil, initial water, and rock matrix, the release of gas from solution occurs as a further drive process. To simplify the calculation of the equilibrium behavior as far as possible, the compressibility equations for the oil, water, and rock phases as well as the real gas equation for the gas phase are used as material laws.

$$V_p = V_{pi} \left(1 - c_f \left(p_i - p\right)\right)$$

$$V_w = V_{wi} \left[1 + c_w \left(p_i - p\right)\right]$$

From the material balance for gas it follows that:

$$\text{Free gas} = (N R_{si} - G_p - (N - N_p) R_s) B_g \tag{2.12}$$

From the displacement process in the pore space it follows that:

$$\text{Free gas} = V_p - (V_w - W_p B_w) - (N - N_p) B_o \tag{2.13}$$

$V_w - W_p B_w$ = net water expansion

$(N - N_p) B_o$ = residual oil volume

Equating (2.12) to (2.13) gives:

$$N R_{si} B_g - G_p B_g - (N - N_p) R_s B_g$$

$$= V_p - V_w + W_p B_w - (N - N_p) B_o$$

Separating reservoir and production terms:

$$N R_{si} B_g - N R_s B_g + N B_o + \frac{N B_{oi}}{1 - S_{wi}}$$

$$\cdot (S_{wi} (1 + c_w \Delta p) - 1 + c_f \Delta p)$$

$$= G_p B_g - N_p R_s B_g + W_p B_w + N_p B_o$$

Combining and rearranging the terms with

$$G_p = N_p R_p$$

gives

$$N \left[(R_{si} - R_s) B_g + B_o + \frac{B_{oi}}{1 - S_{wi}} ((c_f + S_{wi} c_w) \Delta p - (1 - S_{wi})) \right] = N_p [(R_p - R_s) + B_o] + W_p B_w$$

Further rearrangements with

$$\frac{B_o - B_{oi}}{B_{oi} \Delta p} = c_o$$

gives

$$N B_{oi} \left(\frac{B_g}{B_{oi}} (R_{si} - R_s) + \frac{B_o - B_{oi}}{B_{oi}} + \frac{c_f + S_{wi} c_w}{1 - S_{wi}} \Delta p \right)$$

$$N B_{oi} \left(\frac{B_g}{B_{oi}} (R_{si} - R_s) + \frac{c_o S_{oi} + c_w S_{wi} + c_f}{1 - S_{wi}} \Delta p \right)$$

$$= N_p (B_o + B_g (R_p - R_s)) + W_p B_w$$

with

$$c_{eff} = \frac{c_o S_{oi} + c_w S_{wi} + c_f}{1 - S_{wi}}$$

it follows that

$$\frac{N_p}{N} = \frac{B_g (R_{si} - R_s) + c_{eff} \Delta p B_{oi} - \frac{W_p B_w}{N}}{B_o + B_g (R_p - R_s)} \tag{2.14}$$

The ratio N_p/N in Equation (2.14) indicates the recoverable quantity of oil – as a fraction of the oil in place – for the dissolved-gas drive mechanism (first term of the equation) and for the fluid- or rock-expansion drive mechanism (second term of the equation). The third term is normally negligible for reservoirs without an aquifer.

2.3.2. Tarner Prediction Method

A tank model is only capable of describing the energetic aspect of the recovery process. For a complete characterization the adequate inclusion of the flow processes in the porous reservoir rock is absent. Tarner solved this problem by a combination of a material balance and flow equations based on the Darcy law [95].

The calculation is as follows:

For a differential pressure change in the closed reservoir, the expected cumulative oil production is predicted and the cumulative gas – oil ratio calculated by using a gas material balance. To check the accuracy of the assumption, the change in saturation in the porous rock caused by fluid removal and the resulting relative permeabilities for gas and oil are determined. From the flow equations for the gas and oil phases a gas – oil ratio results which is compared with that calculated from the material balance. If the results are identical, the predicted quantity of oil produced during an incremental pressure change is correct. Otherwise, the calculation must be repeated with a new assumption until the two gas – oil ratios are equal.

In the following, the equations for the calculation of the two gas – oil ratios are derived by way of example for a gas-saturated oil reservoir.

Material Balance for Gas. Original gas content = Quantity of gas produced + residual gas

Material Balance for Gas

$$N R_{si} = [N B_{oi} - (N - N_p) B_o] \, 1/B_g$$

Gas cap content

$$+ (N - N_p) R_s + G_p$$

Dissolved gas

$$B_g = \frac{T z p_0}{p T_0}$$

$$G_p = N_p R_p$$

$$R_p = \frac{q_g}{q_0} \quad \text{when } q_g \text{ and } q_0 = \text{constant}$$

Separating the variables:

$$N R_{si} B_g - N B_{oi} + N B_o - N R_s B_g$$

$$= N_p R_p B_g + N_p B_o - N_p R_s B_g$$

$$N [B_o + B_g (R_{si} - R_s) - B_{oi}]$$

$$= N_p (B_o + R_p B_g - R_{si} B_g + R_{si} B_g - R_s B_g)$$

with

$$B_o + (R_{si} - R_s) B_g = B_t$$

$$B_{oi} = B_{ti}$$

it follows that:

$$N [B_t - B_{ti}] = N_p [B_t + B_g (R_p - R_{si})]$$

$$\frac{N_p}{N} = \frac{B_t - B_{ti}}{B_t + B_g (R_p - R_{si})} \tag{2.16}$$

or solved with respect to $N_p R_p$:

$$G_{p1} = N_p R_{p1} = \frac{N (B_t - B_{ti}) - N_p (B_t - R_{si} B_g)}{B_g}$$

The index 1 refers to the gas – oil ratio derived from the material balance.

Change of saturation

$$\text{OOIP} = N B_{oi}$$

$$\text{Residual oil} = (N - N_p) B_o$$

$$V_p = \frac{N B_{oi}}{1 - S_{wi}}$$

$$S_o = \frac{(N - N_p) B_o}{N B_{oi}} (1 - S_{wi})$$

$$S_o = \left(1 - \frac{N_p}{N}\right) \frac{B_o}{B_{oi}} (1 - S_{wi}) \tag{2.17}$$

Dynamic gas – oil ratio equation

$$R_{p2} = \left[\frac{q_g}{q_o}\right]_{T_o, p_o} = \frac{\frac{q_g}{B_g} + \frac{q_o R_s}{B_o}}{\frac{q_o}{B_o}}$$

The index 2 refers to the gas – oil ratio derived from flow equation.

$$R_{p2} = \frac{q_g B_o}{q_o B_g} + R_s$$

Darcy equation (2 immisible phases):

$$q_g = -\frac{k_g A}{\mu_g} \nabla p_g$$

when ∇p_c is rather low it follows $\nabla p_g \simeq \nabla p_o$

$$q_o = -\frac{k_o A}{\mu_o} \nabla p_o$$

$$R_p = \frac{k_g \mu_o B_o}{k_o \mu_g B_g} + R_s \tag{2.18}$$

$$G_{p2} = N_p R_{p2}$$

Each pressure stage can be graphically extrapolated to the convergence of the ΔG_p values or numerically iterated (see Fig. 33).

Figure 33. Graphical method of solution in the Tarner method a) Material balance; b) Flow equation

Figure 34 shows the typical development of the produced *gas – oil ratio* R_p plotted against the cumulative oil produced. The gas – oil ratio curve above the bubble point pressure (1 – 2) is constant; when the pressure falls below p_b then initially no free gas reaches the well as long as the required critical gas saturation is not reached (2 – 3) in the surroundings.

Figure 34. Influence of the critical gas saturation on R_p [88]

Then follows a steep rise of the gas – oil ratio (3 – 4), resulting from the rapid transport of the free gas. The quantity of dissolved gas, which is the source of the gas yield, is limited. Therefore with advancing production time the cumulative gas – oil ratio reaches a maximum, which is then followed by a rapid drop (4 – 5) until the free gas is exhausted. In the last phase of production (5 – 6) it is principally the gas dissolved in the residual oil that is produced.

2.3.3. Reservoir Simulation

The prediction methods discussed in the previous sections are applicable only to problems in which the reservoir can be described by uniform mean properties of the rock and the pore fluids. The individual character of a group of wells or the characteristic drainage volume of their reservoir, and the occurrence of multiphase flow can be described only by reservoir simulation. This entails modeling the whole body of the reservoir and solving, simultaneously or stepwise, the coupled differential equations for pressure and saturation in each of its volume elements. This section can only give a short introduction to the basic principles of the numerical simulation of reservoir behavior. For further details, see [96], [97]. Here the mathematical foundations for an engineering understanding will be treated with reference to two simple models [98].

2.3.3.1. Model for Steady-State Flow

A five-point well pattern with an injection well at the center of the square is taken as the basis. According to symmetry considerations, in a homogeneous formation, only one-eighth of the grid area including the injection well and a production well, need be shown. Figure 35 shows the pattern section dividing the reservoir area into square blocks, the representative portion being bound by two orthogonal sides and the diagonal between injection well and production well.

Figure 35. Grid model for steady-state flow [98]

At the center of each block there is a node at which all the block's properties are concentrated. The flow geometry in all blocks is linear, except for the drainage areas of the two wells. Here, radial flow geometry prevails and, instead of a node, there is an external radius r_e and a well radius r_w, representing the equivalent block boundaries. An incompressible medium is assumed to be injected into well 1 and produced from well 15. Because of the prevailing pressure regime, outflow from the nodes is possible only to the north or east and inflow to the nodes only from the south or west. For steady-state flow it is assumed that for each node the sum of inflows and outflows at every instant is zero. This is illustrated here for node 8:

$$q_{7-8} + q_{5-8} = q_{8-12} + q_{8-9} \tag{2.19}$$

If the permeability is equal in all nodes (i.e., in all blocks) and the areas of flow are likewise identical (since the block width is constant), the general form of flow equation for the Darcy law (see Section 2.2.1.1) can be written as follows:

$$q_i = -\frac{Ak}{\mu \Delta x}\Delta p_i \tag{2.20}$$

Since the coefficients before Δp_i are constant in all terms, Equation (2.21) can be written in place of Equation (2.19)

$$(q_7 - q_8) + (q_5 - q_8) = (q_8 - q_{12}) + (q_8 - q_9) \tag{2.21}$$

For node 8 there then follows the pressure balance set up in Equation (2.21) or rearranged to:

$$q_5 + q_7 - 4\,q_8 + q_9 + q_{12} = 0$$

Such a pressure balance can be set up for each of the 13 nodes, in addition radial flow conditions must be included in the pressure balance for nodes 1 and 15. The 15 equations with 15 unknowns are arranged in matrix form and solved for the pressure values at the nodes with, e.g., the Gauss – Jordan or Gauss – Seidel method. The calculation can also be performed with different permeabilities in the individual blocks.

2.3.3.2. Model for Unsteady-State Flow

If the same model is used, but instead of an incompressible fluid a compressible medium is injected into the well, then, instead of a material balance for the individual volume flows in the nodes, a balance for the mass flows must be set up. As already derived in Section 2.2.1.2 from the mass balance in a cylindrical volume element, a variant of the diffusivity equation must be used to describe unsteady-state flows. For linear flow through the volume element of edge length Δx, the following differential equation can be written for the change of flow along the distance Δx:

$$\frac{kA}{\mu}\left(\frac{\Delta p}{\Delta x}\right)_{x+\Delta x}\Delta t - \frac{kA}{\mu}\left(\frac{\Delta p}{\Delta x}\right)_{x}$$

$$\Delta t = A\Delta x\,\phi c\Delta p \tag{2.22}$$

After separating the variables Δx and Δt, the diffusivity equation for unsteady-state flow is obtained (Eq. 2.23):

$$\frac{\Delta p}{\Delta t} = \frac{k}{\phi \mu c}\frac{\Delta\,(\Delta p/\Delta x)}{\Delta x} \tag{2.23}$$

This differential equation is solved by the finite difference method (→ Mathematics in Chemical Engineering, Chap. 7.3.; → Fluid Mechanics, Chap. 5.1.). In this procedure the pressure gradient $\Delta p/\Delta x$ is regarded as the difference of pressure in two successive segments, divided by the distance between the centers of the segments. Figure 36 shows such a linear sequence of segments.

$$\left|\frac{\Delta p}{\Delta x}\right|_{j-1,j} = \frac{p_j - p_{j-1}}{\Delta x} \tag{2.24}$$

$$\left|\frac{\Delta p}{\Delta x}\right|_{j,j+1} = \frac{p_{j+1} - p_j}{\Delta x} \tag{2.25}$$

$$\frac{\Delta\,(\Delta p/\Delta x)}{\Delta x} = \frac{(p_{j+1} - p_j)/\Delta x - (p_j - p_{j-1})/\Delta x}{\Delta x} = \frac{p_{j+1} - 2p_j + p_{j-1}}{\Delta x^2} \tag{2.26}$$

The pressure gradient between segments $j-1$ and j is calculated according to Equation (2.24), and the pressure gradient between segments j and $j+1$ according to Equation (2.25). The change of pressure gradient between segments $j-1$ and $j+1$ is then shown by Equation (2.26). For unsteady-state processes, the change of pressure in the time Δt is superimposed on the change of pressure with position Δx. In Figure 36, the index j designates the position and the index n the time. In the lower part of the Figure 36 the pressure variation at times n and $n+1$ is shown. If Equation (2.23) is applied in general form to define the pressure variation at the beginning and at the end of the time interval, Equations (2.27) and (2.28) respectively result (see below).

The pressure variation at the beginning of the time interval is given by:

$$\frac{p_{j,\mathrm{n}} - p_{j,n+1}}{t_{n+1} - t_n} = \frac{k}{\phi \mu c}\frac{p_{j+1,n} - 2p_{j,n} + p_{j-1,n}}{\Delta x^2} \tag{2.27}$$

and at the end of the time interval by:

$$\frac{p_{j,\mathrm{n}} - p_{j,n+1}}{t_{n+1} - t_n} = \frac{k}{\phi \mu c} \frac{p_{j+1,n+1} - 2p_{j,n+1} + p_{j-1,n+1}}{\Delta x^2} \tag{2.28}$$

Equations (2.27) and (2.28) can give the same result only when the time interval Δt_n approaches zero. If the pressures at time n in all segments are known, the pressure in element j at time $n+1$ can be calculated with Equation (2.27). This method is known as the *explicit solution method.* The advantage of the explicit solution method is that it is very easy to program. However, it is only accurate if very small time steps are chosen.

In contrast to the explicit solution (Eq. 2.27) in which there is only one unknown, i.e., the pressure p_j at time $n+1$, three unknown values are present in Equation (2.28) at the end of the interval (i.e., p_{j-1}, p_j, and p_{j+1}).

Figure 36. Linear sequence model

If, however, Equation (2.28) is formulated for all three nodes, $j-1$, j and $j+1$, the three unknown pressures can be determined from the three equations. The equations are arranged in matrix form and solved simultaneously either by the Gauss – Seidel or by the Gauss – Jordan method. This procedure is known as the *implicit solution method* and has the advantage of yielding sufficiently accurate results even at quite large time intervals. For modeling problems in multiphase flow, the saturation equation for each block of the reservoir model must be solved in addition to the pressure equation. Hence, the chosen block size of a reservoir model is influenced not only by the availability of geological and petrophysical information but also by the accuracy of the numerical computation method. In regions of the reservoir where relatively rapid changes occur in the transport characteristics – such as pressure gradient, transmissibilities, and saturation changes – fine-mesh grids are necessary for numerical accuracy of the solution method. For complex reservoir studies, simulation models with several ten thousand blocks can be produced which require considerable computer time. There are numerous simulation codes with a dynamicized fine grid size that follows the movement of flood fronts.

Table 3. Types of reservoir simulators

Description	Physical/chemical processes
Multiphase flow simulator	multiphase flow in porous/fissured media solution of gas in oil properties of phases depend on pressure and temperature
Compositional simulator	mixing of phases equilibrium of components between the phases dispersion flow properties depend on interfacial tension properties of phases depend on composition
Thermal simulator	like compositional simulator, in addition : thermal convection, conduction, and radiation flow properties of phase depend on temperature chemical reaction of components of a solid phase (oxidation)
Chemical flood simulator	adsorption/desorption of components retention of phases rheology of aqueous phases properties depend on salt content of the aqueous phase mass transfer between aqueous phase and rock

The powerful computer programs currently available to the natural gas and petroleum industry not only take into account simple processes such as gas dissolution, gravitational force, and capillary pressure effects but also can describe the infuence of compaction in unconsolidated formations and the influence of the diffusion and sorption of components. They can also treat particular rheological properties of the phases, e.g., the structural viscosity of polymer solutions

in polymer flooding the phase behavior during mixing processes, temperature- controlled fractionation of materials (distillation and cracking), thermal conduction, and thermal convection. A survey of common simulator types is given in Table 3.

2.3.4. Statistical Prediction Methods (Decline Curve Methods)

Aside from tank models or flow models to describe and predict reservoir behavior, statistical prediction methods also can be used. These methods are based on observation of the decline of production or pressure in a reservoir; analysis of the mathematical trend; and extrapolation of the decline of production or pressure over the period of prediction. The observed trend curves often show uniform patterns. This is due to the fact that the change in the flow rate is proportional to the pressure change, and the pressure change is linked logarithmically, as a result of the compressibility relation, with the volume removed from a closed system. In many cases, therefore, an exponential decline of the production rate with time can be derived from the trend analysis.

To characterize the decline curve analysis method, some basic definitions are given in advance [98]. The *fractional production decline* is defined as the change of flow rate divided by the initial flow rate

$$-\frac{\mathrm{d}q}{q} = \text{fractional production decline}$$

The change of the fractional production decline with time is called the *production decline rate D*.

$$-\frac{\mathrm{d}q}{q\,\mathrm{d}t} = D$$

In a closed or semiclosed reservoir with no infinitely large, fully active aquifer available for energy replacement, three types of production rate decline can be distinguished:

1) Constant production decline rate:

$$D = \alpha' q^0 \quad \text{exponential production decline}$$

2) Linearly proportional production decline rate:

$$D = \alpha' q^1 \quad \text{harmonic production decline}$$

3) Production decline rate is proportional to a power function of the production rate:

$$D = \alpha' q^n \quad \text{hyperbolic production decline}$$

In order to permit simple prediction methods, the production rate or a function of the production rate is plotted against a function of time or against cumulative production, choosing scales such that straight lines are obtained. The basic method is explained with the aid of exponential and harmonic production declines as examples.

Exponential Production Decline. Figure 37 shows a semilogarithmic plot of the production rate versus time. According to Equation (2.29) the gradient of the straight line is a measure of the production decline rate *D*.

$$D = -\frac{\mathrm{d}q}{q\mathrm{d}t} = \alpha' q^0 = \alpha'$$

after integration

$$\int_{q_0}^{q} \frac{\mathrm{d}q}{q} = -\alpha' \int_0^t \mathrm{d}t$$

$$\ln\frac{q}{q_0} = -\alpha' t = -Dt$$

$$\frac{q}{q_0} = e^{-Dt} \tag{2.29}$$

Figure 37. Exponential production decline, production rate versus time

By combining the variables *q* and *t* a new quantity – the cumulative production N_p – is obtained.

$$N_p = \int_0^{t_{N_p}} q\,dt$$

$$\int_{q_0}^{q} \frac{dq}{q} = -\alpha' \int_0^{t_{N_p}} dt$$

$$\int_{q_0}^{q} dq = -\alpha' \int_0^{t_{N_p}} q\,dt$$

$$q = q_0 - D N_p \tag{2.30}$$

A plot of production rate q versus N_p is shown in Figure 38. From this plot the production decline rate D is also obtained from the gradient. As soon as the production rate of a well falls below a marginal value determined by the cost, production must be stopped. The corresponding cumulative amount produced can be determined graphically by extrapolating the production decline curve to the known limiting production rate q_a. The difference between the maximum cumulative production N_{pa} and the present cumulative production N_p gives the reserves of the well or reservoir.

Figure 38. Exponential production decline, production rate versus cumulative production

Harmonic Production Decline. The defining equation for harmonic production decline is:

$$D = -\frac{dq}{q\,dt} = \alpha' q$$

Initial conditions are: when $t = 0$, $D = D_0$ and $q = q_0$,

$$D_0 = \alpha' q_0, \quad \alpha' = \frac{D_0}{q_0}$$

After separating the variables and integrating

$$-\int_{q_0}^{q} \frac{dq}{q^2} = \alpha' \int_0^t dt$$

$$\frac{1}{q} - \frac{1}{q_0} = \frac{D_0}{q_0} t$$

$$q = \frac{q_0}{1 + D_0 t} \tag{2.31}$$

$$\log \frac{q}{q_0} = -\log (1 + D_0 t)$$

For harmonic production decline, the double logarithmic plot of the production rate against the time function $(1 + D_0 t)$ gives a straight line of gradient -1. Again, if a new quantity is introduced by combining q and t a semilogarithmic relation between production rate and cumulative production is obtained after integration (see Fig. 39).

$$N_p = \int_0^{t_{N_p}} q\,dt$$

$$-\int_{q_0}^{q} \frac{dq}{q} = \alpha' \int_0^{t_{N_p}} q\,dt$$

$$\ln \frac{q}{q_0} = -\frac{D_0}{q_0} N_p \tag{2.32}$$

Figure 39. Harmonic production decline, production rate plotted against cumulative production

With the appropriate plot, a straight line of gradient $-D_0/q_0$ is obtained, that again – if the limiting production rate q_a is known – can be extrapolated to give the maximum cumulative production N_{pa}.

Hyperbolic Production Decline. From the equation for the hyperbolic production decline rate, after rearrangement of the variables and integration, the following relations are obtained:

Initial condition: $t = 0$, $q = q_0$, $D = D_0$

$$D = -\frac{\mathrm{d}q}{q\mathrm{d}t} = \alpha' q^n \qquad \alpha' = \frac{D_0}{q_0^n}$$

$$q = \frac{q_0}{(1 + n D_0 t)^{1/n}} \tag{2.33}$$

$$N_\mathrm{p} = \frac{q_0^n}{(1-n)\, D_0} \left(\frac{1}{q_0^{n-1}} - \frac{1}{q^{n-1}} \right) \tag{2.34}$$

A plot of production rate versus $\log(1 + n D_0 t)$ is given in Figure 40.

The analysis of the production decline can also be based on the fraction of oil in the total production rate or on the water cut in the production, instead of on the oil production rate. The same relations then apply. In order to eliminate the influence of individual measurement inaccuracies or of unrepresentative sampling, it is advisable to integrate or smooth the dependent variables q and the water cut f_w respectively over fairly long periods, e.g., over a month's or year's production. These steps enable improved reliability of the prediction methods.

3. Deep Drilling and Production Engineering

3.1. Deep Drilling Engineering [119–123]

3.1.1. Introduction

To produce raw materials and fuels from the Earth's crust, two basic problems have to be solved: Firstly, the deposit must be discovered, its parameters determined, and then investigated whether it can be developed by considering all the available data (see Chaps. 1 and 2). Secondly, the raw materials present in the deposit have to be produced – i.e., transported to the surface – economically [119]. To solve these problems, particularly for liquid and gaseous materials, deep drilling is indispensable. Boreholes for locating and exploring deposits are known as *exploratory wells*, while boreholes used for producing from the deposits are known as *production wells*. Successful exploratory wells are converted into production wells using suitable equipment.

Exploratory wells must be drilled in such a way that they provide accurate information on the rock formation drilled through and on the deposit to be explored. This is done by sampling the rocks, e.g., in the form of drill cores, sampling the materials present in the rocks (e.g., water, oil, gas), gathering data from a great variety of geophysical borehole measurements, carrying out productivity tests, and then measuring the resulting behavior of the reservoir pressure.

Production wells must be drilled and completed in such a way that the cost of subsequent production is minimal, as much as possible of the reservoir contents can be produced economically, optimum use is made of its productive capacity, a minimum number of wells is required to develop the reservoir and trouble-free production can be achieved, preferably over the reservoir's lifetime [120].

Boreholes compete with mining methods as a means of prospecting for and producing raw material and energy, and are in many cases, superior to them from economic, operational, and safety viewpoints. Deep drilling engineering is therefore becoming increasingly important with th development of deposits and reservoirs that lie ever deeper and in inhospitable regions, under the oceans, or in perpetual ice.

3.1.2. History [124–126]

Deep drilling is far from being a new technology (Fig. 41). As early as 600 B.C. CONFUCIUS reports that wells have been sunk in China to a depth of about 500 m into salt brine with hammer drilling devices. In Europe, both in ancient

times and in the Middle Ages, wells were sunk to obtain water and later for prospecting shallow ore lodes. Development of drilling engineering and well depths that could be achieved stagnated for many centuries. The search for raw materials (potash, iron ore, and coal) in the course of the industrialization in the 19th century forced the development of deep drilling engineering. At that time, drilling depths already reached 2000 m.

In Europe during the second half of the 19th century and the start of the 20th century a extensive search for raw materials took place. It was pioneers like von Oeynhausen, Fauck, Craelius and Anton Raky who encouraged the progression of deep drilling by, for example, developing high-speed rotary percussion drilling with circulating drilling mud. Only then could the frozen boreholes for shaft sinking of mines for coal, potash, and rock salt be produced.

The rotary drilling method, developed in the United States at the end of the 19th century for the exploration and development of oil deposits, was an important step forward. Since then, rotary drilling has been continuously developed and today is still the dominant drilling method by which depths of more than 9000 m have been reached in commercial boreholes. The present depth record has been achieved with the Kola SG 3 well in the Commonwealth of Independent States, which reached a depth of 12 261 m, using turbodrilling.

3.1.3. Rotary Drilling [127–131]

The circulating viscoplastic drilling mud and powerful roller cone drill bits are the most important characteristics of rotary drilling. These, in combination with other typical features, have contributed to the overriding importance of rotary drilling in the exploration and development of deep and high-pressure reservoirs. Spectacular blowouts, which were numerous in the past, are now rare.

The principle of mode of action in rotary drilling is as follows (Fig. 42):

By means of a rotary table (e), a torque is applied to the drill string that consists of individual drill pipes (steel tubes). The drill string is suspended in the derrick by a hook (b) attached to a traveling block. This hook, which allows the drill string to rotate, can be moved vertically with a drawwork on the rig floor. The drill string transfers the torque to the drill bit (n), whose impact on the rock is controllable via the weight of the drill string and drill collars (m) (massive thick-walled tubes arranged above the bit), which is not taken up by the drilling hook.

The rotary table, which is a "surface drive", can be replaced by a hydraulic drilling motor immediately above the bit. This *downhole motor*, which can be a positive-displacement machine on the Moineau principle or a multistage turbine, is installed in the drill pipe and driven by the circulating mud.

Drilling Tool. The drilling tool, which is adapted to the rock through which the hole has to be sunk, performs the drilling work on the hole bottom. This can be done by machine drilling (cutting bit), fragmentation drilling (roller cone bit, Fig. 43 A – E), or abrasive drilling (diamond bit Fig. 43 G).

The key factor with regard to drilling costs is the rate of penetration (v). The rate of penetration depends on the rotary speed of the bit n, the weight on bit P, the drillability of the rock S, and the hole diameter D. In the empirical relation

$$v = \frac{n P^2}{D^2 S^2} k$$

a "drillability coefficient" k combines factors such as rock properties, mud parameters, pressure conditions, bit type, wear of the bit teeth, etc. It is assumed that the hole bottom is clean.

Rotary speed and bit load cannot be increased without limit. However, the "penetration factor", defined as the product of the bit load and bit rotary speed, should be as high as possible.

The *power required* to turn the drill pipe, which depends on the mud lubrication properties, rises with the square of the drill pipe diameter and linearly with the depth. With increasing depth the torque imparted to the bit by a surface drive becomes smaller.

The *bit's mechanical power* is directly proportional to the product of torque and rotary speed. In addition, due to the mud stream emerging from the bit, *hydraulic power* is available at the bit, which is equal to the pump power minus the pressure drops in the mud system.

With limited mud pressure due to conventional borehole and pipe sizes, the optimum hy-

Figure 41. History of drilling depth

draulic power at the bit is reached at ca. two thirds of the power required to pump the mud. The hydraulic power is much greater than the mechanical power, especially with increasing depth. The bit shape, nozzle arrangement, and diameter are chosen so that all requirements for the hydraulic pressure conditions, cleaning of the hole bottom, lubrication, and cooling of the bit, as well as for securing the cuttings' removal capacity are met.

The resistance to the flow of mud on its return through the annulus between drill pipe and borehole wall requires hydraulically optimum compatibility between borehole and drill pipe diameters to achieve minimum resistance to flow. The minimum flow velocity in the annulus should be 0.5 – 0.75 m/s. The pump power must be so designed that sufficiently high pressures and large volumes can be handled.

The drill string is loaded by tension (the drill pipes' own weight), torsion, bending (resulting from borehole deviations), constant or dynamic internal pressure and buoyancy forces, and periodical vibration. In some cases, the superposed stresses in drilling can only be calculated with difficulty.

Drilling Mud. The cuttings are carried in the annulus between drill pipe and borehole wall by the mud. A thixotropic liquid, containing bentonite and cellulose for example, is used as the drilling mud. Its functions include cooling and lubricating the drilling tool and cleaning the borehole bottom, discharging the cuttings, and supporting the borehole wall (hydraulic casing). The mud is pumped with piston pumps through the drill pipe to the bit, from which it emerges at high speed to ensure that the cuttings are removed as completely as possible. The cuttings and finer solids are removed from the mud at the surface and the mud is then recycled by pumping it back again into the hole. Vibrating screens, centrifuges, and hydrocylones are used to seperate the solids (Fig. 44).

The mud parameters (e.g., the rheological properties, the mechanical, and thermal state of the colloid system) are adjusted according to the drilling speed, pump power, bit type, borehole diameter, pore pressure in the rock, temperature, nature of the rock drilled (mud loss zones in the drilled formations), borehole inflows, and solids content.

Mud densities between 1.10 and 1.40 g/cm^3 are usually sufficient for compensating the reser-

voir pressure and the "trip margins", i.e., the piston effect and inertia forces during pulling the drill string. In special cases, however, values below 1 g/cm^3 or up to 2.5 g/cm^3 are also required.

The carrying power of the mud for the cuttings is given by:

$$F\theta = V\,(\varrho_{\mathrm{G}} - \varrho_{\mathrm{m}})\,g$$

where F is the surface area of the cutting particles (cm^2); V the volume of the cuttings (cm^3); ϱ_{G}, ϱ_{m} are the density of rock, and mud, respectively (g/cm^3), g is the acceleration due to gravity (dm/s^2), and θ the static shear stress (dyne/cm^2).

The filtration of water from the mud in porous rock strata, with the formation of a filter cake, proceeds according to Darcy's law of filtration.

Figure 43. Various types of bit

The quantity of filtrate is proportional to the permeability of the filter cake, the applied pressure difference, and the active filter area, and inversely proportional to the filtrate viscosity and the filter cake thickness.

Pressure and temperature changes, particularly in deep holes, make it difficult to assess and calculate the formation of the filter cake. The filter cake can attain a high mechanical strength and cause drilling difficulties. Prolonged filtration can also lead to considerable reservoir damage.

The electrical conductivity of the mud and its pH value and contents of chloride, sulfate, calcium, and hydrogencarbonate ions are continuously monitored. Additives used to adjust the mud system include:

1) Clay materials (e.g., bentonite, attapulgite)
2) Weighting materials (e.g., barite, hematite)
3) Viscosity-lowering substances, dispersants, protective colloids
4) Emulsifiers, lubricants (e.g., oil, to reduce internal friction)
5) Inhibitors

There are water- and oil-based drilling muds. Aside from the technical drilling requirements for the mud, the following requirements should be met: the formations drilled through remain identifiable (mud-logging see below, indication of traces of gas and oil); borehole measurements, tests, core drilling, and other borehole studies can be carried out; the mud causes as little damage as possible to the formations drilled through (obstruction, swelling, mud losses); and corrosion of the drilling equipment is limited.

Drilling muds for use in geoscientific research such as in the German Continental Deep Drilling Program (kontinentales Tiefbohrprogramm, KTB) the main well must satisfy not only the drilling engineering requirements but also those of the geoscientists. For example, such drilling mud must have adequate rheological properties, lubrication, and borehole stabilization without influencing the geoscientific analysis or even disturbing it.

Data on the drilling parameters, mud properties and lithology are collected and stored in a *mud logging system* by modern data acquisition and a computer system for drilling rigs. A network of monitors, work stations, plotters, and printers gives continual access to continuous and discontinuous data and information.

The hole tapers in sections from top to bottom. Each of these sections is secured by means of a string of casing, which is bonded by cementing into the surrounding formation (Fig. 45).

3.1.4. New Developments in Deep Drilling Engineering [131–143]

Superdeep Wells. Commercial wells for hydrocarbons with final depths of at least 5000 m are common nowadays, especially in Europe, where exploration has moved to even deeper strata – at present the Rotliegendes. The technology, especially the control of high pressure and temperature, is essentially available for this depth range. However, considerable development work remains to be done in certain areas, especially to improve the economics of drilling and the operating life of the well.

Superdeep scientific wells such as that of the KTB, which will be more than 10 km deep, represent an intensification of the requirements and hence are of importance for technology development (Fig. 46).

A few degrees' change in the inclination and azimuth of the well bore would cause such large lateral forces, abrasive loads, and wear that the well would have to be abandoned. The 10 000 m drill string is analogous to a wire 1.5 mm thick and 100 m long, at whose lower end a drilling tool has to be controlled with an accuracy in the 0.1 mm range. Active vertical drilling systems have been developed that continuously measure the inclination and direction of the borehole. They pulse the values through the mud to the surface, so that compensatory steering can be applied to the tool by extending hydraulic pistons or ribs (Fig. 47). Straight, superdeep vertical holes are therefore a particularly demanding variant of directional drilling engineering. The size and performance data of the drilling rig for a superdeep hole clearly exceed those for conventional extra-heavy rigs.

Horizontal Drilling. The second main focus of development in deep drilling engineering is directional drilling where the drilling of holes along a defined course over long distances and

Figure 45. Continental Deep Drilling Program (KTB), drilling and casing diagram

Figure 46. Drilling rig UTB 1 for the 10 000 m main well of the Continental Deep Drilling Program (Germany)

at considerable depth in the underground rock is now possible and economic (Fig. 48).

Offshore, virtually all wells are directional drilled holes, and the oil and gas fields are developed with up to 60 wells per platform. *Onshore*, the classical applications of horizontal deep drilling include recovery under residential areas and traffic routes, borehole deviation in the event of damage, and relief wells in the event of blowouts. A directional drilled hole is produced by using mud-driven drilling motors. The deviation is created with a bent shaft (bent sub) combined with the drilling motor, or the motor itself is tilted. In Western Europe, 85 % of the onshore wells are directional drilled.

Inclination and azimuth (i.e., the course of the borehole) are continually measured and the values transmitted to the surface via pressure

Figure 47. A) Active steering vertical drilling system; B) Cross section of X;
a) Flex sub; b) Data pulser; c) Sensors; d) Top stabilizer; e) Electronic pack; f) Generator; g) Control valves; h) PDM – downhole motor; i) Nonrotating body; j) Hydraulic pistons with movable ribs; k) Rotating shaft; l) Drill bit

pulses through the mud column. From the surface the azimuth can be corrected accordingly. The continual checking, known as *measuring while drilling* (MWD), is crucial for success. The azimuth is measured by magnetometer or, if in the neighborhood of ferromagnetic masses, by gyro compass. The inclination is evaluated by accelerometers (pendulum). In addition, these instruments indicate the tool face, i.e., the angle between the desired direction and magnetic north (notch and bead). The availability of powerful, slow-running drilling motors together with the MWD technique are prerequisites for successful directional drilling engineering.

The inclination build-up of a hole to be deviated into the horizontal can be abrupt or gradual (see Fig. 49). At an inclination change of 10°/10 m, the resulting deviated section has a radius of 6 m, whereas at 1°/10 m, the radius is ca. 600 m. Holes have been deviated to reach destinations of up to 3000 m, and holes exist which have been drilled horizontally for almost 1000 m.

3.2. Investigation of the Reservoir Rocks [144], [145]

With suitable drilling tools, rock samples (mud samples, drill cores) are obtained from the reservoir rock zone and can subsequently be examined comprehensively. Special geophysical measurement (logging) and the first, brief productivity tests (drill-stem tests) are also carried out.

Core Drilling. During core drilling, the drilling bit (full-hole bit) is replaced by a core barrel with crown (ring bit). Single- or double-tube core barrels are used, some with diamond-type cutter heads. Single-tube core barrels have the drawback that the core is directly exposed to

the mud (core losses); With doubletube core barrels this is prevented by the inner tube of steel or rubber (Fig. 50). Wedgejaw catchers, flap catchers, or combinations of both prevent the core from falling out. Orientation devices and core markings allow an accurate determination of inclination (dip), course (strike), and pattern of the strata drilled through.

Since 1985, remarkable successes have been achieved by a combination of rotary and mining drilling methods. The *mining drilling method* involves rapid rotational drilling with thin-lipped diamond crowns and a double tube core barrel. Externally and internally smooth drill pipe is used which almost fills the whole borehole cross section. After boring out the core, the inner core barrel is left on the cable (wireline coring), so that the bit can remain on the bottom until it is worn out (Fig. 51). The thin-lipped crown and thus the distinctly smaller area of rock which has to be destroyed, makes greater drilling progress possible in comparison with rotary drilling technology. With the combination of both methods the drilling progress can be doubled with complete core recovery; by use of the wireline technique, the number of round trips can be reduced; and by use of a rotary drilling rig, the time for the round trips can be reduced.

Aside from core drilling, cores can also be shot, drilled, or cut (slicer) from the borehole wall.

Figure 49. Horizontal drilling strategies
A) Conventional; B) Drainhole, medium radius technology; C) Drainhole, short hole technology

The *core investigations* provide measurements on pore filling, pore volume, liquid saturation, capillary pressure, wettability, grain sizes, chemical composition, petrographic relationships, and strength, etc.

Geophysical Borehole Measurements. Continuous coring is impossible for economic reasons. Geophysical borehole measurements allow the continuous determination of rock parameters, especially the porosity, the original saturation conditions, the nature of the pore fluid, the type of rock, the mineral composition, and the bed thickness.

The laboratory examinations of the core samples taken point-by-point, however, take longer.

A variety of instruments is available for borehole measurements. The methods used can be divided into four main groups

1) Electrical methods: macroresistance, microresistance, conductivity, scanner technique, dip meter
2) Sonic measurements: sonic velocity, travel time, amplitude, reflection, refraction
3) Radioactivity measurements: natural, induced gamma, and induced neutron radioactivity, spectral analysis
4) Determination of geophysical fields: temperature, pressure, stress, magnetics, Earth's gravitation

The temperature limit of application of geophysical methods is ca. 250 °C, corresponding to about 8000 m borehole depth.

The data from borehole measurements are subjected to comprehensive and complex methods of interpretation, for which powerful computers and specialists are required. The results obtained describe the rock, its pore filling, and the geology in situ. Greater reliability is obtained when more drilled rock material from cores and cuttings have been used for calibration and correlation of the measurements.

Tests. In (productivity) tests, qualitative and quantitative conclusions about the inflow process from the formation to the well are obtained in order to decide whether a well allows economic production. At the start of a test, the formation interval to be examined is isolated from the rest of the formation in order to exclude possible effects from other beds and mud pressure. After pressure relief of the interval, the rate of flow to the well, the pressure, and temperature are measured and plotted as a function of time. The inflow into the drill string is then stopped and the pressure build-up which then occurs is recorded. A second flow cycle is initiated by reopening the drill string.

In principle it is also possible to use a test device on a self-supporting electric cable. Here,

however, the inflow rate is strictly limited for design reasons, so that only zones near the boreholes can be tested.

In order to save the casing costs of wells which may later, prove to be uneconomic, tests are carried out in the uncased borehole during or immediately after the end of the drilling operations. For stability reasons, the test duration in the uncased and therefore unbalanced, unstable borehole (drill-stem test) must be kept short, whereas in later capacity tests in the cased hole the test duration is theoretically unlimited.

The interpretation of the measurements must provide information on the following important parameters:

1) Initial reservoir pressure
2) Flow pressure as a function of the amount produced per unit time (productivity index)
3) Shut-in pressure
4) Reservoir and borehole temperature
5) Permeability and permeability capacity
6) Drainage radius of the well
7) Location of formation damage

During these tests, samples of the reservoir contents are also obtained, so as to carry out chemical and physical studies. The results serve as a basis or aid to planning decisions on: the completion of the well, well and reservoir treatments, the production method, the surface installations, the further development of the field, and exploitation strategy.

3.3. Casing and Cementation

Casing [146]. The casing of a borehole usually consists of several concentric strings of casing pipe, which are installed according to the geological – engineering requirements at different depths (Fig. 42). It protects the borehole wall against scouring and blowouts, seals permeable horizons to prevent undesirable inflow or outflow, and prevents sloughing from the formation

into the hole. The casing is in part already inserted during the drilling operation, in order to protect problem sections of borehole. It represents a considerable cost component of the well.

With *exploratory wells*, the planning of the casing program is rather difficult, since knowledge of the formation is still imperfect. For *production wells* a standard program is usually set up, in which tube dimensions, wall thicknesses, and landing depths are optimized.

The casing can either be run to the surface and landed in the wellhead, or hung in the borehole as a so-called liner in a string of casing already installed in the borehole. To ensure a tight bond between casing string and formation, the casing is cemented, either up to the surface or only over a certain length of the borehole.

The casing is subject to a multiplicity of loads, which generally arise in combination:

1) Differential pressure between the outside and inside due to hydrostatic pressure and the pressure of the fluids in the pore space
2) Radial component of the formation stress
3) Tensile stress from the string's own weight, especially during installation
4) Bending stress in holes with changes of direction, especially in horizontal holes
5) Thermal stresses

Since the individual stress contributions superpose one another, precise assessment of them e.g., by landing under tension, is essential. A series of standardized material grades and casing joints is available to meet the requirements.

Tubing String. The tubing string transports the fluid produced to the surface. The tubing is landed in the wellhead at the surface and anchored, if necessary, at the lower end. The annulus between casing and tubing can be sealed with a packer if the conditions in the well require it. *Packers* are usually elastically deformable sealing elements (of elastomers), which are so combined with peripheral sliding wedges that during up and down movements the wedges grip, the seal deforms, and the annulus between tubing and casing is sealed. Tubing, like casing, is manufactured in a range of standardized material grades and dimensions.

Cementing [134]. The cementing of the casings serves the following purposes:

1) Massive bond of casing and formation, in order to divert the forces resulting from the loading of the casing into the formation, i.e., absorption of the axial and radial stresses which act on the casing string
2) Isolation of permeable formations, in order to prevent flow between different rock strata and, in particular, the contamination of the groundwater
3) Corrosion protection of the casing

The cement is mixed with water to form a cement slurry, and a wide variety of additives are added to control the rheological properties, the setting time, the final strength, etc. The slurry is then injected with high pressure pumps through the borehole into the annulus between casing and formation.

The cements used in the oil and gas industry are standardized according to API. Table 4 gives some important characteristics of various API cements. Aside from the cement quality, the technical execution of the cementing is of crucial importance for the quality of the cement sheath. For control, the *cement bond log* is used: this is an acoustic measurement method for determining the bonding of cement and casing or of the cement with the formation.

For cementing at high temperature, Class G cements are used, to which SiO_2 flour is added to avoid a decrease in compressive strength and an increase in the permeability of the cement. The effect of the added SiO_2 depends on the formation of hydration products, for instance according to

$$2\,Ca(OH)_2 + SiO_2 \rightarrow 2\,CaO \cdot SiO_2 \cdot 1.25\,H_2O + 0.75\,H_2O$$

The elevated temperature lowers the hardening time, so retarders and antifriction agents must be added.

3.4. Production Engineering [148], [149]

3.4.1. Objectives [150–153]

The purpose of the exploitation and production planning of hydrocarbon reservoirs is to produce optimum amounts of saleable (transportable) products at minimum cost and with close attention to all aspects of safety and ecology. In initial

Table 4. Characteristics of some API cements [147]

	Class

stages of field development, with few wells and few drill-stem and production tests available, the base for planning is not valid enough. However, the data obtained from continuous production and field development lead to continual refinement of production planning, in which reservoir and engineering are regarded as a synergism. Only in this way can an optimum overall technical and economic result be achieved.

Production engineering has to solve the following problems in *oil production*:

1) The time for water injection – when not using it to adjust the pressure above the bubble point (see Section 3.4.3) and/or for adjusting the dynamic level to below a certain material stress, corresponding to the fatigue endurance limit of the pump rods
2) Dependence of the productivity index (IPR) on viscosity of the oil and water cut
3) Gas production and availability in the gas lift method (see Section 3.4.3)
4) Advantages and disadvantages of the artificial lift methods

and for *gas production*:

1) Occurrence of toxic and/or other problematic substances, e.g., hydrogen sulfide, elementary sulfur, carbon dioxide, nitrogen, which requires complex process engineering installations (see also, → Natural Gas)
2) Heterogeneous multilayer and selective water incursion

The safety and ecological aspects have always been important; nowadays it is preeminantly so. In the second half of the 19th century, a blowout was proof of discovery after finding the reservoir by drilling and a reason for celebration. Thanks to the continual improvement of technical equipment and the regular training of technical staff, blowouts have become rare, but they can never be totally avoided due to human error.

Over wide areas, oil and gas production engineering have common principles, which are treated in the following section whereas specific questions of production engineering for oil are dealt with in Section 3.4.3, those for gas in Section 3.4.4.

3.4.2. General Production Engineering

General production engineering encompasses completion, setting up production, perforation, well and reservoir treatment, fracturing technology, workover, the inflow – performance relationship, one- and two-phase flow through tubing and lines, safety engineering, environmental protection, and the plugging and abandonment of wells.

3.4.2.1. Completion

If, after borehole measurements and tests, a well is considered worth producing from, it is completed, i.e., it is equipped with all technical installations necessary for production (Fig. 52). Components necessary for the completion are the wellhead (including flanging), casing, cementing, tubing string or strings (single or multiple completion), and the "bottom hole completion". This includes the special equipment used in the reservoir zone, i.e., liners, liner hangers, sand filters, packers, and all the "wireline equipment" which can be operated by cable and wire.

Bottom Hole Completion. Essentially two types of well completion exists in the zone of the producing formation (pay zone), open-hole completion or casing and later perforation (perforated casing) (Fig. 53).

Open-hole completion, in which the producing formation is not cased, is only rarely used. Especially with fairly thick, poorly consolidated formations and at high production rates, difficulties arise with the penetration of sand from the formation into the well.

For this reason, the *casing is set on top of producing formation or below* it and cemented. To allow the production fluid to enter the well, the casing and the cement sheath are then perforated in the reservoir rock zone.

3.4.2.2. Perforation [154]

By perforating the casing and cement sheath, the well is hydraulically connected with the reservoir, so that the production fluid can enter the well with the least possible pressure drop. Currently, shaped charges are exclusively used for perforation. They are introduced into the borehole on a self-supporting cable and ignited. The number of perforations, their arrangement, penetration, and size depend on the rock hardness and borehole conditions.

With the hollow-charge perforators mainly in use, the penetration depth in the rock is 10 to 40 cm, depending on the compressive strength of the rock (Fig. 54).

Normal shaped charge perforators can be used up to ca. 170 °C. For higher temperature, special explosives and techniques have been developed. These explosives are so designed that they do not detonate by self-ignition when overheated but become unusable as a result of decomposition to gaseous phases. Explosives

stable to high temperature such as hexanitrostilbene (HNS), can be used at up to 250 °C and depths down to 8000 m for up to 24 h downhole time. In the high-temperature range which is sensitive to misfiring, safety measures prevent the effects of stray and leakage currents on the charges.

Pressure on target $p_1 = 35$ kPA (5×10^6 psi), velocity of foreward jet $v_1 = 6100$ m/s

The method of *tubing-coupled perforating (TCP)* (Fig 55), which has been available since ca. 1980, has captured a significant market, because of the fairly large number of deep gas wells and the rapid development of horizontal drilling. By this method the charge carriers are installed on the tubing string below the packer and landed with the latter. They are then connected (wet) in a separate run with an ignition mechanism on the cable, and then ignited. The advantages of this method are

1) A greater shot density – 39 shots per meter with the TCP instead of 13 shots per meter conventionally
2) Considerably longer perforation sections, since the load limit of the cable used in conventional perforation is no longer limiting
3) No hanging of the charge carriers in the inclined hole (> 70°)
4) Greater safety, because the charges are sensitized underground

3.4.2.3. Well and Reservoir Treatments [155–158]

The treatment of the well and of the reservoir formation is intended to increase the productivity of wells. The decrease of this productivity can stem from the drilling process or arise in the course of production. *Well treatment* is intended to restore the original state or, in other words, to restore an inflow to the well free from restrictions. *Reservoir bed treatment* is aimed at a sustained increase of the flow through the reservoir rock.

Well Treatment. The type of obstruction of the well must be known in order to choose the most suitable treatment from the various possibilities. The obstruction can be caused

1) By solids from the mud (filter cake)
2) By increased water saturation around the well (water block)
3) By swelling of the clay minerals present in the rock's matrix
4) By chemical precipitation
5) By emulsification

In practice the first two causes occur most frequently. The obstructions are usually removed by chemical treatments. The most important chemical treatment agents are: aqueous solutions of hydrochloric acid (5 – 15 wt %), hydrofluoric acid (1 – 6 wt %), acetic acid, citric acid, and surfactants (all in concentrations of 0.1 – 5 wt %).

Corrosion inhibitors are added to the acids. *Hydrochloric acid* is generally used with carbonate-containing reservoir rock. Whose carbonate content should be ca. 20 %. The hydrochloric acid partly dissolves the rock. *Hydrofluoric acid*, usually in conjunction with hydrochloric acid, is used for dissolving silicates: here, the hydrofluoric acid is added to the hydrochloric acid as NH_4HF_2.

Surfactants are added in almost all well treatments in order to promote the dispersion of the solids, to improve the wettability of the rock, and to prevent emulsification.

Figure 55. Tubing-conveyed perforation (TCP)

If it is intended to treat only the *borehole wall*, it is sufficient to circulate the treatment liquid into the well zone in question. If the obstruction *extends into the reservoir bed*, e.g., by clay swelling, the treatment liquid must be uniformly injected into the reservoir, avoiding pressure which leads to cracking. In any case, the reaction products should be removed from the reservoir bed or from the well as quickly as possible.

Reservoir Bed Treatments. Two methods basically exist for extensive improvement of the inflow conditions in a reservoir bed of low original permeability:

1) Pressure acidizing (usually in carbonate rocks)
2) Hydraulic fracturing (frac treatment)

The best-known method of reservoir-bed treatments is fracturing technology (Fig. 56), which is mainly used for producing artifical flow paths in the reservoir rock.

Pressure acidizing is also a hydraulic fracturing method by injection of acid. In pressure acidizing, however an increased permeability is achieved, by dissolution of a part of the carbonate matrix along the fracture faces. In *frac treatment* oil, water, or acid are injected together with gelling or viscosity-enhancing agents. In addition, to hold the fractures open and thereby ensure a high-permeability flow path, a proppant (e.g., fluvial, natural quartz sand) is added while pumping in the liquids. This proppant is deposited in the fracture and so produces the high-permeability artificial flow path. The reservoir treatments are very highly developed and so make it possible to solve very specific problems. The fracturing process will be treated briefly in the following:

Fracturing. In fracturing, only a part of the injected liquid is available to widen the fracture and act as a medium for transporting the proppant, or for the chemical reaction along the fracture faces. With a widening fracture, the other part of the liquid increasingly migrates into the pore space of the rock. In order to limit this effect, which is unfavorable for the success of the operation, *fluid loss agents* are added that raise the viscosity and form a filter cake. These agents cause the initially high fluid loss to decrease substantially after the filter cake has built up. Later,

Figure 56. Schematic of fracturing technology
A) Before fracturing; B) After fracturing

these additives become ineffective due to the influence of temperature and pressure, and the production stream reaches the well unhindered.

In order to ensure the success of reservoir bed treatments, a sufficient depth of penetration into the reservoir rock must be achieved. This penetration depth must be greater with less permeable reservoir rock. Penetration depths of 40 – 70 m are usual with vertical or horizontal fractures.

The development of deep (ca. 5000 m), low-permeability gas reservoirs in the Rotliegendes and Carboniferous has led to remarkable developments of this technology. New developments now include a temperature-stable and sufficiently viscous supporting fluid, the availability of pressure-resistant proppants, and powerful equipment. For example, a treatment volume of 1100 m^3 requires a fracture length of 300 m, maximum pressure of 750 bar at a depth of 4200 m, and 15 pumping units with an output of 9000 hp.

3.4.2.4. Workover

An important chapter of constant concern for the production engineer is workover technology. More than 10^6 production wells worldwide, of which three quarters are oil wells, require continual upkeep and maintenance and – repeatedly during the course of their use – repair. Thus the number of workover hoists is three to four times the number of drilling rigs. In addition, there are the modern systems, i.e., the wireline technique (lowering activation of tolds by wireline), the coiled tubing technique, and hydraulic lifting and lowering of the strings with the snubbing unit. Workover should always follow a sequence of diagnosis, therapy (work program), operational execution, and monitoring of success. Reliable measurement techniques and supervision of operation and production are the prerequisites for correct diagnosis. The *workover hoist,* equipped with rotary table or power swivel and pump unit, can carry out the functions of lifting, lowering, rotation, and circulating fluid, likewise the *snubbing unit*. With the *wireline technique*, only running in and out is possible. The *coiled tubing* (Fig. 57) enables lifting, lowering, and circulating. Rotation is possible by using suitable downhole motors. The coiled tubing technology has a high technical standard and a growing market, particularly also with regard to horizontal drilling. Coiled strings with diameters of 1 inch (2.54 cm), $1^1/^4$ inch (3.18 cm), $1\ ^3/^4$ inch (4.44 cm) and 2 inch (5.08 cm) are available, and can be used at a depth of up to 5500 m and in combination depending on the loading situation.

3.4.2.5. Horizontal Wells [132], [135]

Horizontal drilling, which has been developed to a state of maturity since the beginning of the 1980s, makes great demands on production engineering (see page 60). Drilling engineering is able to produce, horizontal drilled sections of a few hundred to more than 1000 m in any rock. In the deviation to the horizontal, the inclination build-up can be abrupt or gradual (Fig. 46). Whether this value is 10°/10 m (final radius 60 m) or 1°/10 m (final radius 600 m) is very important for the subsequent completion.

The essential reason for the rapid growth of horizontal drilling is that a markedly larger

Figure 57. Schematic of a coiled-tube unit
a) Drive unit; b) Operator's cabin; c) Coiled-tube drum; d) Coiled tubing; e) Injector crane; f) Injector head; g) Preventer device; h) Wellhead

zone of the reservoir is developed for production than with vertical wells, so that a considerable (15 – 20-fold) production increase is achieved at lower differential pressure; better sweep efficiency; and a higher recovery. In heterogeneous, fissured rock the effect is even more significant. The potential, especially if specific enhanced oil recovery (EOR) processes are incorporated in this technology, is far from exhausted. In gas reservoirs, turbulence around the borehole is avoided, and in underground storage, a capacity increase of 3- to 8-fold seems possible with horizontal drilling. There is still, however, a considerable need to develop devices and methods specific to the process, cf. Schlumberger coiled-tubing-logging (CTL). Completion in deviated and horizontal wells can be carried out as follows:

1) Open hole (i.e., uncased): only possible with stable formations
2) Open hole with slotted or "prepacked" liner (i.e., plastic-reinforced sand filter)
3) Slotted liner with external casing packers (ECP) in the open hole
4) Cemented and perforated liner

With the first two methods, no isolation of unwanted sections is possible. However, the use of correctly placed ECP's (method 3) and successful cementing (method 4) allows selective production. For liner installation, the clearances and the borehole geometry in the deviation zone and the permissible bending stress must be taken into account. Cementing in the horizontal section is impeded by the fact that the gravitational force favors segregation of liquid and gas at the top and sedimentation of cuttings and solid at the bottom. For the perforation, only the TCP technique (see Section 3.4.2.2) is possible from a 70° inclination; and, as an alternative to the tubing string, coiled tubing or the drill string. The wireline technique in horizontal holes is virtually ruled out. For workover, the coiled tubing technique mainly is applied (Fig. 54). Methods independent of the borehole inclination are suitable as production facilities such as the submersible centrifugal pump, the hydraulic piston pump, and gas lift. The lengths of rigid units must be geared to the maximum possible flexure in the deviation zone, and the necessary adaptation of systems must be carried out.

3.4.3. Oil Production Engineering [159–163]

In oil production engineering, not only the technical instruments and developments determine success. Efficiency and overall profitability crucially depend on qualified supervision, damage evaluation, the logistics of material and distribution, and a sound operating organization. The use of *tertiary methods* (e.g., steam injection and steam flooding) signify additional tasks for production engineering: In *steam injection wells*, and also in the hot production wells of the *steam flooding projects,* extreme thermal stresses (140 bar, 340 °C) and corrosion problems in the underground equipment must be kept under control.

Production engineering has powerful production processes and production facilities available to it. Herewith, the particular conditions of each reservoir can be taken into account. This in turn

enables, firstly, the reservoir fluids to be produced as efficiently as possible with extensive use of the reservoir energy; and secondly, production difficulties, caused for example by accumulated sand or water or by corrosion, to be obviated in good time.

With the opening up and development of a reservoir, its most important qualities are determined: reservoir pressure, permeability of the rocks, viscosity of the production fluid, and the presence and characteristics of a natural water drive. These are the foundations for planning production rates and methods, and equipment.

In principle, the following production processes are available:

1) Flowing production
2) Gas lift
3) Centrifugal pumps
4) Piston pumps, sucker rod, or hydraulic

With these methods, ca. 3.25×10^9 m^3 crude oil per year are produced from depths of up to 6000 m.

Flowing Production [156], [164]. As a result of production, a pressure drop occurs which expands, funnel-shaped, around the hole. Under the influence of this pressure gradient, the reservoir liquid flows to the borehole, enters the casing through the perforation holes, rises up in the tubing string to the surface, and flows at the surface by lines to a collection manifold at a central plant. Here the output from the field is combined, dewatered, treated, and transported to the refinery. The flow pressure at the depth of the reservoir bed is sufficient to overcome the hydrostatic pressure of the production column and the frictional loss in the tubing string and in the surface lines.

The *flowing production rate* is calculated as a function of bottom flow pressure, tubing diameter, and pressure head according to the law of conservation of energy, while taking into account the empirical parameters which determine the two-phase flow.

The relationships become more complicated when the pressure in the tubing string falls below the degassing pressure (bubble point) and free gas evolves (see Section 2.2). Progressive pressure reduction gives rise to larger gas bubbles (see Fig. 58) and the liquid column breaks up (slug flow, Fig. 58 C), or the rising gas bubbles entrain oil drops which, owing to friction at the tube walls, form an upward-moving film (annular flow, Fig. 58 E) which finally changes into mist flow, i.e., the liquid film disappears and the liquid separates into droplets which are mixed with the gas stream (Fig. 58 F).

Figure 58. Flow patterns in two-phase flow
A) Bubble flow; B) Bubble flow (turbulent); C) Slug flow; d) Froth Flow; E) Annular flow; F) Spray flow

The duration of this economically advantageous eruptive production phase can be extended by a good matching of the production rate to the tube cross section.

Gas-Lift Production. In the gas-lift method, gas is injected into the tubing string at one point or – to minimize the starting pressure – at several successive points and in this way bubble or slug flow is initiated, as has been described for eruptive production (see Fig. 59). This method is used continuously or intermittently, depending on rate of flow, production rate, and gas availability.

The eruptive production phase is often already supported with gas lift or is switched to gas lift when the pressure gradient between borehole

Figure 59. Continuous gas-lift operation
A) Schematic; a) Annulus; b) Valves closed; c) Tubing; d) Valves open; e) Production zone; B) Pressure distribution at different depths; a) Annulus pressure; b) Pressure curve in tubing for production well; c) Pressure curve in tubing for inoperative well

and reservoir decreases. The applicability of this flexible production method is limited when there is a shortage of gas or the gas compression costs are too high. Where sufficient gas is available, the scope for application is wide because of the flexibility of this method with regard to production rate and depth. In strongly deviated boreholes and if abrasive media are coproduced, gas lift is usually superior to other production methods (no moving parts).

Gas lift valves controlled by the injection pressure are fitted in the tubing string, into which they inject the lift gas. The pressure at the valve is controlled via a pressure bellow which operates with or without spring support (according to type). At the surface before installation the bellow is set to a certain opening and closing pressure.

Since on start-up of a well in gas-lift operation, the back-pressure of the whole liquid column requires a high injection pressure, several lift valves are installed and distributed over the tubing string, whose opening pressures are coordinated with each other.

Production with Subsurface Pumps
[165], [166]. Subsurface pumps are the most widespread form for the production of the oil, which is usually contaminated by considerable amounts of water. Types of pump used include electric submersible centrifugal pumps and mechanical or hydraulic subsurface piston pumps. The pumps are installed below the liquid level in the wells and, in difficult underground conditions, must overcome hydraulic heads of several hundred to a few thousand meters (Fig. 60).

Electric Submersible Centrifugal Pumps (Fig. 57 B). These are multistage centrifugal pumps that are submerged in the production liquid. They are installed in the borehole, directly coupled with the motor, and suspended on the tubing string. The pump unit comprises from bottom to top: electric motor (bipolar asynchronous squirrel-cage, oil-immersed, j), centrifugal pump (with numerous stages e, f), protector (sealing adaptor between motor and pump, k), gas separator (for separating free gas from the produced liquid, l), electrical switching device, and power cable (these limit the installation depth, since the electric insulation resistance is temperature dependent).

The hydraulic head (hydrostatic pressure), frictional pressure losses, and wellhead pressure determine the number of pump stages. Because of possible changes in the hydraulic head, pumps with stable characteristics are preferred.

At depths between 1000 and 4000 m, submersible centrifugal pumps cope with minimum delivery rates between 260 and 50 m^3/d

and maximum delivery rates between 340 and 150 m^3/d.

Mechanical Rod Subsurface Pumps (Sucker Rod Pumping [167]) (Fig. 57 A). Oil production was for a long time synonymous with the use of rod pumps, which are installed as tubing pumps with the tubing or are landed at the pumping depth as inserted pumps on the pump rods in the tubing string. These pumps are driven from the surface by beam pumping units with motor, gearing, and a pumping jack, that includes the typical walking beam with "horse's head" on which the pump rod string is suspended. The weak point of the system, the "pump rod string", requires particular attention. Liquid load, rod string weight, vibrations, and mass acceleration, which occurs particularly when the direction of motion reverses, determine the efficiency and the limits of this kind of artificial lift.

The supply of types of subsurface pumps that differ according to material, valve arrangement, piston area, and stroke length also take account of extreme operating conditions. Valve function and pumping efficiency are periodically checked by dynamometer measurements, i.e., by recording the load uptake. Corrosion, sand, or friction in deviated wells reduce the service life of pumps and rod string.

Hydraulic Subsurface Piston Pumps (Fig. 57 C). Like the electric submersible centrifugal pumps, these pumps are run underground, yet by high-pressure fluid. The difficulties with the pump rod string are avoided by hydraulic transmission of the automotive energy with an auxiliary liquid from the surface to a pump installed in the borehole. A high-pressure pumping installation provides the "power oil" that is supplied to the individual producing wells and the pump via the tubing string. The pump combines

two identical sections in one block, the upper of which operates as a motor which is driven by pressure oil (f) and for its part drives the lower pump (g) which is hydraulically in complete equilibrium.

The pressure oil is either taken from the produced oil and carefully cleaned (open system) or is contained in a closed system. Usually the pressure oil is supplied down the tubing and the flow back through the annulus or, where that is not possible, it is fed through additional tubing strings. For repairs, the liquid stream is reversed and the pump pumped to the surface (free pumps in contrast to fixed pumps).

The range of application of hydraulic piston pumps exceeds that of rod pumps by far. As with gas lift, a number of wells are connected to one power oil high pressure pump station, respectively, so that an additional system of lines is required. To account for the particular conditions of each well, a specially devised flow and pressure control system is required.

With the electric submersible centrifugal pumps and rod pumps, neither additional lines above ground nor an expensive control technique are used. These basic differences are significant for economic efficiency [168].

Developments and Limitations. In addition there are *jet pumps* (mainly in the United States); *Moineau pumps* with subsurface drive or driven by pump rods from the surface; and *turbine-driven submersible centrifugal pumps.* However, these pumps are rarely used. The proven methods described above maintain their position, thanks to their high standard of technical maturity and reliability. The correct choice of pump for the pressure and inflow conditions (inflow performance) and the flow resistances in the production path (outflow performance), both determined by the reservoir, and the product composition (gas, oil) ensures a long and optimized service life. An example of this is Shell Oil's Reno field in Wyoming in the United States. There, since 1975, 190 wells at depths ranging from 2000 to 4000 m have been converted from hydraulic piston pumps to rod pumps for economic reasons alone. By using combined pump rod strings of high-strength steel, a further developed heavy-duty beam (Mark II) drive, and subsurface pumps suitable for the great depths, 105 m^3/d wet oil with 30 % water are produced from 4420 m lifting depth. The field is monitored by electronic dynamometers.

3.4.3.1. Collection and Treatment of Crude Oil [146]

Production rates, crude oil properties, and field conditions determine in what way and to what extent the production of individual wells, groups of wells, parts of the overall field or several neighboring fields are combined. Treatment at the field includes gas separation and dewatering (Fig. 61).

Gas Separation. The degassing process starts already in the reservoir and intensifies with the decrease of pressure and temperature through the tubing string and the pipe system during production. Consequently, a two-phase mixture enters the gas separators. To obtain a maximum liquid yield and, in particular, at high gas – oil ratios, a multistage separation should be aimed for. However, apparatus cost and special requirements, such as, e.g., gas delivery at high pressure to the consumer, lead to the widespread use of two- and three-stage separation.

Dewatering and Desalting. Since crude oil can still be produced at 95 % water content, water – together with sand and contaminants – is removed as early as possible to reduce transportation costs and corrosion. The refinery acceptance standard in Germany limits the total contamination (water and sludge) of the crude oil generally to 1 % (salt content below 0.02 %). The water separates only partly as "free water." Water and oil mainly occur as an emulsion, which must be broken by thermal, mechanical, chemical, or electrical methods, or by a combination of these. At the same time, the emulsifiers present in the crude oil (constituents that are concentrated at the interface) must be made ineffective. The free water droplets must coalesce and, with the aid of gravitational or centrifugal forces, separate.

Since the 1980s, a greatly simplified water separation method has evolved from the variety of process combinations used. Particular features of separation plants are:

1) Early feeding of the demulsifier in order to use the pipeline for internal mixing

Figure 61. Flow diagram of an oilfield
a) Compressor; b) Drying; c) Line; d) Gas separator; e) Heater; f) Separator; g) Desalter; h) Tank; i) Secondary sedimentation; j) Filter

2) Moderate heating ("cold treatment") to save thermal energy and reduce the vaporization losses
3) Simple apparatus; the water separation can often be carried out in a single tank, whereas previously a downstream fine purification in the gas-heated treater or an electrical fine purification has been required

These improvements have been made possible by the further development of demulsifying chemicals and by continual constructional improvements. These include also the improvement of the gas separation, by which the inconvenient degassing after processing has been eliminated.

3.4.3.2. Special Problems in Crude Oil Production

Paraffin Precipitation. When the crude oil is cooled below the pour point, high-boiling hydrocarbons can precipitate and lead to clogging of the tubing string or the output lines. Countermeasures are internal plastic lining of pipes, hot oil treatment, additions of chemical inhibitors to the oil, and periodic cleaning of tubing and lines with scrapers or go-devils. Incompletely removed paraffin precipitates are often the reason why reservoir bed treatments and measures to improve the inflow are unsuccessful.

Chemical Precipitates. Impurities such as carbonates, sulfates, and sulfur can impair production, treatment, and water injection by obstructions in the reservoir, sealing of the perforation, and narrowing of lines to the point of shutdown.

Sand. Fine sand from the reservoir bed can considerably hinder operation of the pumps and cause damage by blocking and increased wear. Countermeasures are:

1) Borehole measurements for the early detection of danger and the subsequent establishment of a safe production rate which must not be exceeded.
2) Retention of the sand by filters consisting of slotted tubes which can be wound with one or more layers of wire or jacketed with a cylinder of plastics-reinforced sand. When the product liquid flows into the filter, the entrained sand is filtered off, and then it deposits and/or fills the annulus between filter and borehole wall. This effect is also achieved by artificially jetted and injected sand packings (gravel pack, frac pack). The

slot and mesh widths of the filters and the particle size composition of the gravel packings must be carefully matched to the particle size of the entrained sand and the flow rates.

3) Artificial sand consolidation by two-component resins that are injected into the formation. Shrinkage during the consolidation or flushing (flooding after gelling) ensures the necessary permeability. Failures can force the abandonment of a well.

Corrosion. Well production and oilfield installations are exposed to corrosion both externally and internally. External corrosion results from aggressive soils or parasitic electrical currents and internal corrosion from salt water, carbon dioxide, or hydrogen sulfide contained in the produced fluids. Parts of a plant particularly at risk are those in which attack by corrosive media takes place in the presence of mechanical stresses, for example, rod strings and subsurface pumps in high water cut wells. Salt water dramatically lowers the fatigue strength of steels under dynamic conditions. Lines and tanks are protected cathodically and/or by addition of suitable inhibitors to the liquid.

3.4.4. Natural Gas Production Engineering [169–172]

Characteristic features of natural gas production engineering are reservoir depths of more than 5000 m (Fig. 62), the completion problems connected with this, and the technically safe control of the accompanying gases hydrogen sulfide, carbon dioxide, and nitrogen. To avoid stress corrosion cracking induced by hydrogen sulfide, *sour gas wells* are provided with completions that ensure the circulation of solvents and/or corrosion inhibitors. Selection of appropiate materials plays a crucial role for casing and completion. Large treatment plants remove environmentally damaging hydrogen sulfide by gas scrubbing (Grossenkneten) and the nitrogen by liquefaction (Clenze) (see also, → Natural Gas, Chap. 2.3.1., → Natural Gas, Chap. 2.6.).

High pressure and high pressure differentials, extreme temperature differences, and aggressive gas constituents require special attention in the production equipment of gas wells. The gas is kept away from the actual borehole casing by the production equipment (Fig. 49) which, in the simplest case, consists of tubing and packer. The necessity of complete and durable sealing makes extremely high demands on the material and of machining precision. For gas wells, special gas-tight tubing joints have been developed. In the selection of tubing and its joints, the large stress resulting from high pressure and temperature changes, causing large load reversals, must be taken into account.

The evolvement of reservoir pressure with time, its depth, the inflow area of the well, the expected production period, and the possible liquid yield during production determine the selection of tubing size and consequently the production rate.

Packers seal off one or several producing zones from each other and from the annulus. The sealing materials used must be temperature-stable, permanently elastic, and gas- and H_2S-resistant. For the further security of the well, the annulus is usually filled with a protective liquid (inhibited water).

Essential elements of the *tubing string* are devices for well-engineering operations, for the control and monitoring of production, and for remedial measures, such as the injection of inhibitors or agents against hydrate formation. These devices are installed, pulled out, and actuated on the wire line. Multizone completions, borehole repairs, selective test and treatment operations, the killing of wells, and gas-lift production require the selective, manipulable opening of the tubing string. For this purpose sliding side door couplings are installed, which are also actuated with tools on the wire line.

Production is *controlled and monitored* by control valves and measuring sections. It is generally controlled as a function of rate or pressure. The rates are determined by orifice meter measurements. (Fig. 63).

Safety is particularly important. At the *surface*, for example, the valves are normally kept open via a low pressure gas system. If the pressure drops in the sensor system, these valves close the production line. With *underground safety valves*, a safety valve kept open via a hydraulic control line closes the tubing string as soon as the pressure in the control line falls. Other arrangements prevent the freezing-up of control devices and lines at the surface by hy-

drate formation, and protect the surface installations from excessively high pressure.

Numerous exhausted natural gas fields are converted into natural gas *deep storage reservoirs*, where demand and suitability allow. (→ Natural Gas). Production engineering questions are also very important for storage reservoirs, especially since withdrawal rates at up to ten times the production rate of a gas deposit are aimed at.

3.4.5. Offshore Recovery [168], [173]

Liquid and gaseous hydrocarbons in reservoirs under the sea bottom are recovered and produced by equipment and devices which correspond in

principle to those of onshore installations. A distinction is made between supporting structures designed to incorporate *drilling rigs* used only temporarily, and those to incorporate *production and treatment facilities* which must be installed in the sea over the whole period of exploitation of the deposit, frequently more than 20 years.

Because of the difficult environmental conditions and of the danger to the staff from the processing of highly inflammable hydrocarbons in a very small space (especially gases), the safety requirements for offshore units are particularly high.

The positioning of the *supporting structures* over the defined locations in the sea no longer presents difficulties in principle, since a very wide range of navigation systems, such as satellite, Doppler, and radio navigation can be used.

Offshore wells require, for the distance between sea bottom and platform, a special string of casing known as a *riser*, which must resist the weather conditions, the motion of the sea, and the current. With exploration in ever deeper water, *platforms* are being built and operated in ocean depths down to 600 m (Fig. 64) and development and planning is already geared to ocean depths ca. 1200 m. The riser technology has also been pushed ahead; the safety engineering aspects of continuous well monitoring under extreme weather conditions being a priority. For the Shell Offshore East Coast Project a riser of 4000 feet (2121 meters) is planned in connection with a dynamically positioned drilling vessel. In deeper waters, in areas with shipping lanes, and for smaller fields, *subsea completion* is sometimes used, in which wellhead and manifold are directly on the sea bottom.

Supporting Structures for Offshore Drilling Rigs (Fig. 65).

Barges were the first constructional systems used for installing drilling equipment and are still in use. These consist of flat hulls which are sunk (flooded) in several storeys above each other in shallow water regions. Such installations must not be exposed to currents and waves. The barge platforms are preferably used in coastal swamp and mud flat regions, inland seas, and similar locations. These installations can be used to water depths of up to ca. 10 m. They are dismantled by refloating the barges.

Fixed Platforms. These are working platforms erected over the surface of the sea on piles rammed into the bottom. Sometimes it can be appropriate that only the derrick is erected on such a platform, while the remaining equipment, materials, energy plants, crew accommodation, etc., are accommodated on a ship anchored nearby. The field of use of these platform – ship installations extends to ca. 30 m depth of water. However, this combined construction method can be used only in regions without difficult currents and weather conditions.

Jack-Up Platforms (Fig. 62 B). Jack-up platforms are flat, multi-storey barges that have three, four, six or more legs. As soon as these hulls have been towed to their place of use, the legs are generally lowered vertically into the sea bottom. The platform is raised on the legs so far above the sea floor (which must be stable) that storm waves of maximum height 32 m (measured in centennial storms) cannot beat under the hull of the barge.

These platforms are equipped for a payload of a few 1000 t of material, depending on their operating location. The derrick and all necessary auxiliary equipment, such as a generator (electric drive for the rotary table, hoist equipment, and mud pumps), cementing, and mud installations, measurement services, etc., are permanently installed. Crew rooms and a helicopter landing deck are necessary support facilities.

Material is transferred from the supply ships by permanently installed rotary cranes. The field of application of such rigs extends to about 100 m depth of water. Because of good stability, the dependence of operations on the weather is very small.

Semisubmersibles (Fig. 62 A) are floating offshore platforms that can be self-propelled. The work platform rests on 3 – 8 slender columns, which themselves rest on two long, parallel floats. The latter are usually submerged to 6 – 9 m during transportation to the location, to give more favorable sailing conditions. At the location, sea water ballast is taken on and the draft increased to about 20 – 25 m to lower the center of gravity. This results in small movements with the heaving swell which together with the reduced water plane area prevent large amplitudes of motion when in the drilling condition.

In addition, the semisubmersible is anchored to its location. Despite the use of these measures

Figure 64. Supporting structures for offshore production plants

Figure 65. Mobile offshore drilling rigs
A) Submersible, water depth to 300 m; B) Jack-up platform, water depth to 100 m; C) Drill ship, water depth to 500 m

there is an increased effect of waves and storms on these rigs compared to other offshore units so that servicing is more restricted than of the units previously described. The main fields of use are water depths between 50 and 600 m. The variable deck load reaches ca. 5000 t, depending on type. The engineering installations required are the same as those of the jack-up platform.

Drillships (Fig. 62 C). Drillships were used very early in offshore engineering. Conventional ships were converted by erecting the derrick amidships and also accommodating the other engineering installations on the ship. Under the derrick a square recess (moonpool) was provided to make drilling possible. Gradually special drillships with different shapes have been built for very diverse applications. However, drillships are used only in small numbers since, owing to their large motions with the heaving swell and despite dynamic positioning over the borehole, they can be used only to a limited degree on the open seas and oceans.

Demand also plays a part. Because of their greater hydrocarbon expectation, it is mainly the shelf edges which have been explored up to now, and the deep sea hardly at all, so that drillships have largely been dispensed with. But they offer considerable advantages in regions with fairly stable weather, because of their high transit speed and fairly large carrying capacity (and therefore small dependence on external supply).

The deep sea drillships "Joides Resolution," and its predecessor the "Glomar Challenger" have undertaken studies of the deep sea bottom and its underground as part of a broad program of geoscientific research.

Drilling rigs on fixed production platforms are used in fairly deep waters where a field has already been explored by other drilling rigs and a larger number of production wells must now be drilled. These platforms are already prepared for later production. More than 40 holes can be drilled fanwise, directed to defined target points. The production installations for the extraction of the hydrocarbons are installed later as required with the aid of rigging-up ships.
